Injections of Aniline Oil in Tuberculosis.—DR. C. E. BRUCE gave the results of some experiments which he had been making in the treatment of pulmonary tuberculosis on Ward's Island, by injections of aniline oil hypodermically. There being some objection to fuchsin or other single preparation of the aniline dyes, it had occurred to him to employ the aniline oil from which these were made, by incorporating it with sterilized olive oil. He made a five per cent. solution, of which he injected five minims, running the dose up from day to day according to circumstances, as high as thirty or more. A much larger amount had been attained in a trial case. The cases were of advanced phthisis, over twelve in number; there was always some reaction, temperature rising to about 101° F.; the sputa became less tenacious, more easily expecto-

rated; the dyspnœa, stridulous cough, and general distress abated, the appetite improved, and in almost all the cases there was a gain in weight. That the aniline preparations had a wonderful influence on pyogenic conditions present on the surface, as in suppurating buboes, carbuncle, etc., was undoubtedly true; and he thought the agent, used as he had described, might exert some germicidal effect.

The Society then adjourned, after which a collation was served.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 10, 1890.

J. West Roosevelt, M.D., President, in the Chair.

Azoospermia.—Dr. Charles Heitzman reported one of these rather rare cases, and exhibited a specimen of the seminal fluid under the microscope. The fluid had come from a German, thirty-three years of age, who had been sent to him for examination by Dr. F. W. Lilienthal, with the following history: The patient had been a masturbator from his seventeenth to his twenty-seventh year; had had gonorrhea three times, the first time for six months with accompanying epididymitis on the left side. He was sexually excitable, had a small penis, and markedly small testes. No remains of the epididymitis. He had been married two years, and his wife had not been pregnant. Microscopical examination of his semen revealed the following features: a few phosphatic crystals, a few red blood-corpuscles, a few so-called testicular elements, a large number of urethral epithelia, a moderate number of globular and oblong corpuscles looking like the heads of spermatozoids, numerous delicate, mostly straight filaments, looking like the débris of spermatozoids, but not a single fully developed spermatozoid. The bulk of the semen was composed of mucus. A second case had come under his observation during the past week, in another German, forty-eight years of age, under the care of Dr. Louis Heitzman. This man had likewise had gonorrhœa and left-sided epididymitis, the epididymis being still indurated. The penis and testes were normal in size. He had been married four years, and his wife was sterile. In this case the seminal fluid appeared crowded with minute fat granules, a few red blood-corpuscles, a few so-called testicular elements and filaments, like broken tails of spermatozoids. No phosphatic crystals, no spermatozoids. As to the causation of azoospermia, Dr. Heitzman considers it a congenital disturbance in the formation of spermatozoids, but not as a result of an epididymitis, which affects only the conducting apparatus of the testis. In his opinion, based upon the study of the development of spermatozoids in rats, the filaments arise in the interior of the epithelia of the seminiferous tubules, by a direct transformation of the filaments of living matter held in the epithelia, after a preceding fusion of a row of epithelia into an elongated protoplasmic mass. The portion nearest the tubular wall is changed into heads of spermatozoids, the central portion, on the contrary, being transformed into the tails. Some of the epithelia escape such a transformation, and appear as the so-called testicular elements. Absence of fusion of the tubular epithelia would explain the appearances in azoospermia, where the heads are destitute of tails, and the latter look as if broken up into small thread-like pieces.

In 1873, Dr. Heitzman published a description, in which he said that every article of what had been called protoplasm had a delicate reticulum of living matter, every particle of which was endowed with all the properties of life which had hitherto been attributed to protoplasm in general. The existence of this reticulum had been shown by untouched photo-micrographs made by Strycker, and advanced histologists admitted the correctness of this description. Previous observers had thought that there were specific spermatoblasts, while he claimed that this reticulum in the epithelia became directly transformed into the spermatozoids with the exception of a few protoplasmic masses, usually spoken of as "the testicular elements."

The President said that this theory, that the fusion of cells produced on the one hand the head, and on the other the tail of the spermatozoids, was most interesting, and merited careful consideration and discussion.

Tuberculosis Limited to the Bronchial Lymph Nodes.—Dr. W. P. Northrup presented a case of this description. A female child, aged three years, born in the maternity wards of the New York Foundling Asylum, was taken sick with measles, early becoming croupy, giving evidence of its diphtheritic nature in the pharynx, soon requiring intubation, and at last developing pneumonia. After an illness of six days it succumbed, and presented on autopsy these interesting peculiarities, viz., tuberculosis limited to the bronchial lymph nodes. The nature of the process has been substantiated by finding tubercle bacilli in the small and large cheesy masses in the nodes grouped at the bifurcation of the trachea. These opaque white masses were plainly seen at autopsy, the size varying from a millet seed to a pea. No other tubercles could be found anywhere in the body after careful search.

The remaining notes of the autopsy are of no special interest. The child was well nourished; its diphtheritic exudate extended from the tip of the epiglottis to the finest branches of the bronchi. Bronchial nodes, about half a dozen in number, were tuberculous, only two of them, however, were extensively cheesy. The remaining nodes were slightly enlarged and contained small discrete masses of varying size. There was extensive recent broncho pneumonia, but no tubercles were in the lungs. This case was unique in his experience. He had long hoped to find this condition, for a large majority of cases had given fairly plain evidence that their oldest tubercular process was in these nodes. He believed that a collection of the cases recorded in the dead-book of the New York Foundling Asylum would give, with this case, an unbroken series illustrative of the theory that, by far the largest percentage of cases of general tuberculosis had their earliest infection in the lymph nodes clustered about the root of the lungs.

General Tuberculosis with Extensive Necrosis of One Lung.—Dr. Northrup also presented specimens from such a case. A male child, aged five months, was returned from the Out-door Department of the New York Foundling Asylum, with the diagnosis of pneumonia. In addition to the pulmonary lesion, it had marked intestinal disorder, the two giving a temperature of 103° and 104° F. The diarrhœa and temperature gradually subsided, so that on the fifth day the thermometer registered 101–99.5° F., and on the eighth day, 98.5° F. The first notes of the case record that at the right apex in front there were fine râles, bronchial breathing, dulness almost amounting to flatness, with fair resonance. The diagnosis at this time was apex pneumonia with unusual signs. Two weeks later, the signs were not yet certain, and, from the extreme dulness, the diagnosis was inclined to favor encapsulated fluid at the anterior upper front of right lung. There was absence of respiratory murmur, marked dulness behind as well as in front; râles in axillary region elicited by coughing, at the same time the resonance below both in front and behind continuing fair. A needle was passed into the region of anterior dulness and brought away a few drops of turbid fluid, which showed under the microscope recent pus-cells. This was thought to justify the diagnosis already made, of encapsulated empyema, but the quantity of fluid seemed strangely small. Another puncture behind, below the angle of the scapula, brought a few drops of pus, but even less than anteriorly. An operation was not considered advisable, and after about two weeks more without elevation of temperature, and with gradual failure of flesh and strength, the child died. At the autopsy, no superficial enlargement of the lymph nodes was found. There was general tuberculosis.

The chief point of interest was in the upper lobe of the right lung. In its anterior portion, involving the pleura, and fusing it with the costal pleura, was a large tuberculous mass containing a central sphacelus. The latter was lying loose in the cavity opened in removing the lung, was irregularly disk-shaped, one and one-half inch thick, and cheesy, crumbling at its margins. On manipulation, the cheesy mass easily came out of its bed, disclosing a cavity with an irregular floor strewn with crumbling cheesy pieces, with several openings admitting a probe, which found its way out through the larger bronchi to the main bronchus. The remainder of the upper lobe was pneumonic and contained tubercle-tissue. The lower lobes of the right lung were somewhat congested. The left lung was normal. The bronchial lymph nodes of the right lung and right side of trachea, at its bifurcation, were enlarged and softened in their centres. One especially large one was situated close against the right apex, resting upon the largest bronchus leading to the cavity. No opening could be detected between them. The cheesy and diffluent glands about the root of the lung were conspicuously near the necrotic area, but there was living tissue between these glands and the cavity containing the sphacelus. This living tissue was densely infiltrated with tubercle-tissue, and the vessels and bronchi leading to the cavity passed through the tubercular mass. Within this small sphere was included all the tubercular process, lung and nodes. Which was the older, the lymph-nodes or the lung necrosis? The case demonstrates the possibility of tuberculosis developing first in the lymph nodes at the root of the lung. Numerous specimens presented by Dr. Northrup to the Society had made conspicuous the fact that the oldest process may be limited to the nodes, while only the most moderate spreading of the process in the immediate vicinity had taken place. He had presented one specimen showing a tubercular inflammation surrounding and closing up an artery at the base of the brain, with softening and destruction of the region which it supplied. The oldest process was probably in the large cheesy and diffluent nodes. From there the process spread by continuity of tissue to the lung, in which one or more were embedded. The thick, dense tubercular inflammation involved the vessels supplying the region of the necrosis, shut off the blood supply, and caused death of the mass, resulting in the sphacelus. With this wholesale destruction of tissue, it is easy to believe that bacilli escaped into the general circulation, resulting in the general infection and consequent development of recent, discrete miliary tubercles of the brain, liver, spleen, and kidneys. Numerous specimens presented to the Society had shown cavities varying in number and size, in children's lungs, but a case like this one had not come under his observation before.

There is a record of a similar abscess of the upper right lobe, involving nearly its entire extent, in a nine months female child. This child was anæmic and had a slight cough. There was no history of pneumonia. Nine days before death she was taken with measles, and subsequently developed some diarrhœa. On autopsy there was extensive pneumonic consolidation, the only aerated portions in both lungs being the middle lobe of the right, and posterior portion of the opposite lower. In addition to the abscess referred to above, there were tubercular, cheesy, enlarged glands at the roots of the lungs, and tubercles in the liver, spleen, kidneys, mesenteric glands, with tubercular ulcers of the intestines. The tubercles in the organs other than the lungs, were few in number, and fine.

Dr. Heitzman said that he had seen such cases of primary tuberculosis in the lymph nodes. He had specimens in his collection from one case in which there was considerable enlargement of the bronchial nodes, which by pressure caused extreme dyspnœa and death.

Dr. Northrup remarked that his paper was based upon his own personal experience, and out of about two thousand autopsies, this was the first instance in which he had met with this condition. In answer to a question from Dr. Biggs, as to why the condition found in the specimen could not be explained as the result of coagulation necrosis, rather than on the assumption that the arteries were plugged, Dr. Northrup said that he had thought the explanation necessary in order to account for the extensive destruction of tissue without liquefaction.

Dr. H. M. Biggs said that this case was quite in harmony with the observations reported by Dr. H. P. Loomis, in regard to the primary involvement of the bronchial lymph nodes. It was not uncommon to find, in adults whose lungs showed no evidence of tuberculosis, cheesy and calcareous bronchial nodes.

The President said that he would like again to bring distinctly before the Society the question of the direction of the lymph currents, about which nothing definite was known. The answer to this question might enable us to determine the course of the bacilli from the nodes to the lungs. Occasionally cases were found in which there were cheesy tuberculous masses in different parts of the body along with tubercles of the pulmonary pleura, but without any evidence of tuberculosis in the remaining portions of lung. The theories usually advanced to explain the mode of infection of the lung with tuberculosis were exceedingly crude. Dr. Roosevelt had devoted two years of hard work to this subject, and had not found a single instance in which there was definite proof that the tubercle bacilli had been introduced by inhalation, and had lodged at any point beyond the main bronchi. We knew nothing definite concerning the manner in which the large majority of cases of pulmonary phthisis were contracted, and there had been absolutely no explanation for the occurrence of pulmonary phthisis in the upper lobes of the lungs in about ninety-five per cent. of the cases, whereas in about eighty per cent. of cases of pneumonia of the infectious type the lesion was in the lower lobes. There was some evidence pointing toward the digestive tract as a common channel for tubercular infection, and this should direct our attention not so much to the dust we inhaled as to the quality of our food.

Dr. Northrup had found that in a very large percentage of cases of general tuberculosis in children, the tuberculous process occurred earliest in the bronchial lymph nodes.

Endothelioma of the Pleura.—Dr. H. M. Biggs presented specimens of this rare condition. They were removed from a man sixty-six years of age, who, nine years ago, had some pulmonary trouble which was supposed at that time to be tubercular. He recovered from this, but about six or seven months ago his health began to fail without any symptoms of any definite disorder. Two months ago a slight cough developed, and a subsequent examination of the chest showed thickening of the left pleura. One month later, a small quantity of fluid was found in that pleural sac. The process was supposed to be tubercular, but no examination of the sputum was made, and no fluid withdrawn at that time. During the last ten days of life he failed rapidly, and the fluid quickly increased in the pleural cavity. Sixty-six ounces of bloody serum were removed from the left pleural cavity, but he died very suddenly on the evening of the same day. The autopsy revealed an endothelioma of the pleura. Dr. Biggs had only seen one other instance of this condition, and in that case there was a similar history, except that it was of much longer duration. The pleura in the present case was considerably over one-half an inch in thickness at one or two points, and on section a thick mucoid substance could be scraped from its surface. The process involved the whole left pleura. The right pleura showed old adhesions and cheesy masses with fibres of new formation around it, evidently tubercular, and probably dating back to 1881, when he had the attack of localized pulmonary trouble. The bronchial lymph nodes were also very greatly enlarged. There were a large number of nodules in both lungs, about eight or ten in the liver, and one or two in each of the kidneys. Some frozen sections

had been prepared and were exhibited under the microscope. Histologically, the tissue of this growth was composed of irregularly branching, apparently anastomosing tubules filled with large, flat, nucleated cells. The other case to which he had alluded was that of a lawyer of this city, who was admitted to the New York Hospital for what was apparently pleurisy with effusion. The fluid accumulated rapidly after each aspiration, so that he had been aspirated six times before he was discharged from the hospital. It was not thought advisable to continue the tappings lest the fluid might become purulent. Some months later, he came under the speaker's care, suffering from dyspnœa due to effusion in the pleural cavity. The fluid was then hemorrhagic. He was aspirated from time to time during the next six or eight months, and altogether he was aspirated fourteen times within a period of about two years. Before his death a large mass developed along the free border of the ribs on the left side, and some fluid accumulated in the peritoneal cavity. The dyspnœa became more severe, and was not even relieved by the removal of the fluid. He died apparently from asphyxia. At the autopsy the pleura was found to be enormously thickened, and a large mass was found attached to the cartilages of the floating ribs on the left side; the whole of the peritoneum was covered with new-growths, and the pericardium and right pleura were filled with the same nodules. About half a dozen small growths were also present both in the lungs and in the liver. These growths presented a similar structure to that exhibited in the specimens just presented.

Tubercular Meningitis Following Operation for Osteitis of the Shoulder.—Dr. V. P. Gibney presented the proximal end of the humerus, which had been removed from a boy eleven years of age. He had been admitted to the hospital on October 1st, suffering from dry osteitis of the shoulder. An incision was made anteriorly with the intention of excising the bone. On drilling into the bone a collection of pus was found. The opening was enlarged and curetted thoroughly until all diseased bone was apparently removed, and the opening was large enough to admit the index finger. A drainage-tube was inserted and antiseptic dressings applied. After about two weeks the tube was withdrawn, and the sinuses continued for a while to discharge slightly. On November 30th, or about six weeks after the operation, tubercular meningitis developed. The boy was attended through this illness by Dr. L. E. Holt, who also made the autopsy. The other specimens were to be presented at some other time. The specimen showed that the cavity which had been entered and drained extended into the joint itself, but the glenoid cavity was almost intact. An interesting question in connection with the case was, "Did the operation precipitate the attack of meningitis?" It had seemed to him that, as the wound had healed so kindly and the patient had recovered from the operation without any bad symptoms, the meningitis developing after this rather long interval could only be considered as a coincidence.

Tubercular Osteitis of the Femur.—Dr. Gibney also presented a specimen illustrating tubercular osteitis of the head of the femur. He had removed it a few days ago from a boy, and the progress of the case since the operation had been satisfactory. This tubercular osteitis had developed when the patient was only four months of age, and a similar disease appeared last fall in the left knee. The specimen was a good illustration of the reparative process. Dr. Gibney referred briefly to another case in which extensive destruction of bone was found at the time of operation, which was performed notwithstanding that there was no grating in the joint.

Dr. Northrup said that tubercular meningitis was a frequent occurrence in the course of any chronic joint disease, independent of the question of operation.

The President thought the specimen showed that the general system had been pretty well excluded from the field of operation, and that it was very improbable that the operation had anything to do with the development of the meningitis.

The President exhibited a lung which had been prepared by a special method, by which its color and elasticity had been wonderfully preserved. The specimen has been prepared nearly a year before, and yet it could be readily inflated with air to the full extent, and on removing the pressure of air it would contract to the same extent as a fresh lung. Its normal elasticity was so well preserved that the same pressure of air was sufficient to inflate this specimen as was required for the inflation of the lung when in the fresh state.

The Society then adjourned until January.

Stated Meeting, January 14, 1891.

J. West Roosevelt, M.D., President, in the Chair.

The Lung from a Case Treated by Koch's Lymph.—Dr. H. P. Loomis presented a section of a lung, which had been removed by Professor Virchow from a case which had died while under treatment with injections of Professor Koch's "lymph." The portion of lung from which the section had been taken had been obtained by Dr. C. E. Quimby. The patient was in an advanced stage of phthisis, and had received at the Charité Hospital a number of large injections of Koch's fluid. No history of the case could be obtained. From the conditions presented at the autopsy it was hardly right to assume that these injections were the direct cause of death. The section which Dr. Loomis presented was taken from the upper lobe of the lung, and included a portion of the pleura, with an old tubercular nodule situated beneath it. The air-cells surrounding this nodule were seen to be the seat of an intense catarrhal pneumonia, and large epithelial cells with a few pus-cells almost completely filled the alveolar spaces. Many of the air-cells near the edge of the specimen were filled with granular matter, presumably derived from degenerated blood corpuscles, for the capillaries throughout the specimen were intensely congested, and in a few of the alveoli red blood corpuscles were to be seen. The terminal bronchi in the section presented evidences of an extensive bronchitis. The pleura was thickened, and the old and new capillaries in it were packed with red blood corpuscles. No foci of softening, nor eruption of fresh tubercles were seen. A section of the lung stained with fuchsin and Bismarck brown showed tubercle bacilli in the centre and about the periphery of the tubercular nodule. The nodule itself was unaltered, and showed the characteristic appearances of an old tubercular process. Such intense congestion, and so acute a pneumonia were suggestive features in the specimen.

Structure of Pus Corpuscles.—Dr. Charles Heitzman exhibited under the microscope pus corpuscles showing the reticulum of living matter, and also showed a photograph taken by Strycker with the electric microscope showing this structure.

A Dermoid Cyst.—Dr. George C. Freeborn presented gross and microscopic specimens taken from such a case. He exhibited one half of a dermoid cyst which had been removed by laparotomy from a woman, aged thirty. The cyst had very thin walls, and was completely filled with a mixture of sebaceous matter, hair, and desquamated epithelium. The interior of one-half of the cyst wall was perfectly smooth, and he was puzzled to find the source of the large quantity of sebaceous matter until he discovered in the other half of the cyst wall a small papillary growth growing into the lumen of the cyst. On microscopical examination it was found to be a mass of modified skin. Resting upon the cyst wall was normal subcutaneous tissue, containing sweat glands, nerves, vessels, etc., and nearer to the apex of this mass the skin was much modified, the sebaceous glands predominating. The history, so far as it could be obtained, was that the tumor had been first noticed about six years

ago, and that the growth since then had been slow. The white sebaceous matter was the product of this small piece of modified skin which had been attached to one side of the cyst wall.

The Society then went into executive session.

Correspondence.

MEDICAL CANNIBALISM VERSUS PROFESSIONAL HONOR AND PERSONAL DIGNITY.

To the Editor of the Medical Record.

Sir: The two articles recently published in the Medical Record, entitled "Medical Cannibalism," and "Should a Poor Man Study Medicine?" are worthy of a careful consideration. The term "Medical Cannibalism" may possibly seem, to some of our professionally well-meaning brethren, slightly harsh, but when we recall their jugglerries and wire pulling tricks, employed solely for the purpose of individual gain, or self-aggrandizement, we behold not only ample justification for the use of the words, but sincerely regret that their iniquitous motives cannot be seen by all mankind

What care these base cannibals that human life falls a prey to their legerdemain, or that the sufferings of mankind are increased instead of being diminished? The editor of the Medical Record has directed our attention, in an article headed "Should a Poor Man Study Medicine?" to the fact that medicine formerly stood on a higher plane. Then a thorough knowledge of medicine was the great essential to individual success, and afflicted humanity was the recipient of its power; but to-day the aspirant for place must be a not over-sensitive "hustler." We regretfully admit the truth of all the statements made in these articles, and at the same time feel constrained to add, that not even one-tenth of the crimes committed by medical cannibals are here brought to light. Their homicidal policy has reduced the gross amount paid for medical attendance in some of our large cities, during the last thirty years, more than fifty per cent., and during the same period it has unquestionably proportionally increased the mortality and human suffering in their clientèle. This is the dark side of the medical profession of the present day. The medical cannibals are merely excrescences on the noblest body on earth. They are of parasitical origin, and found to thrive in certain limited areas of our civilization, while the great body of our profession is still in a perfectly healthy condition, maintaining their professional honor and personal dignity. The practical questions now presented for solution to the honorable members of our profession are: What are the causes of this prostitution? of the development of these semi malignant growths; and likewise, what are the agencies which can be employed for their destruction? I cannot fully agree with the author of the article "Should a Poor Man Study Medicine?" who says: "It is of course, the dispensary evil," although I am perfectly willing to admit that this is one of the degrading agencies. A careful analysis of the subject, however, carries me back, and at the same time suggests the propriety of asking a few pertinent questions bearing on this inquiry. It must, I think, be admitted by all fair men that the immediate cause of this moral degradation has its origin in the inordinate greed and desire for self aggrandizement. The same agency has caused the multiplication of medical colleges in our country far beyond any necessity, has lowered the standard of medicine, and in many instances these institutions are directly chargeable with the parentage of medical cannibalism. How are these institutions commonly originated? Is it not true that in the majority of instances a small medical coterie, or in some cases even an individual physician, takes all the preliminary steps—procuring a charter, etc.? The charter having been obtained, is it not then in order, for the same party who procured it, to select a few of his personal friends, with but little if any reference to their knowledge of medicine, to act as professors? Does not the same party who procures the charter, virtually appoint the trustees for the institution? Are there not well-known institutions organized as stock companies, where the appointment of the professors is solely dependent on the amount of stock the applicant will purchase? Are not many of our hospitals, ostensibly established for the preservation of human life and the relief of human suffering, placed under the control of incompetent physicians and surgeons—medical cannibals—who by their legerdemain secure from the governing boards these coveted plums? Is not the same question equally applicable to the regularly organized dispensaries with their governing boards? Why, then, does the author of "Should a Poor Man Study Medicine?" when speaking of the evils which beset our profession, remark "It is, of course, the dispensary evil? The profession is not overcrowded—that is to say, it is not overcrowded with good men—but the competition with the dispensaries is too great for most men to struggle against with any hope of success."

The homicidal policy, "or Medical Cannibalism," is therefore justly chargeable to the corrupt management of medical colleges, hospitals, dispensaries, and likewise a scarcely less potent agency found in many of the so-called beneficiary societies, where the chief object of the organization seems to be to procure medical attendance and medicines without adequate payment. I have now directed attention to some of the most potent agencies in the prostitution of the medical profession. This has been a comparatively easy task, but is it possible to suggest a remedy which will banish the parasitical growth? The destruction of these semi-malignant excrescences requires that the remedy should be applied to the disease wherever it is found. It will not do to spare the rich and influential, while we torture the poor, friendless miscreants.

Frail humanity finds comfort in pointing to the moral degradation of others, especially when violence has been done to an individual's conscience, and the higher the worldly position of the associate criminal, the greater is the satisfaction afforded the "tender-foot." It is true that this sort of self commiseration does not amount to a moral, or even logical, vindication of a criminal or wrong action; but, nevertheless, we are familiar with the effect of a bad example on even those who desire to act justly. We still remember the verse learned in our boyhood days:

> "Vice is a monster of so frightful mien,
> As to be hated needs but to be seen.
> Yet seen too oft, familiar with her face,
> We first endure, then pity, then embrace."
> —Pope's Essay on Man.

It is quite evident that the proper *esprit de corps* is largely wanting among medical men in some parts of our country. How can this be gained? Much could be advantageously done in this direction by the professors in our best medical colleges, if they would direct the attention of their students during their lectures to the importance of maintaining the honor and dignity of our profession. In this manner the proper *esprit de corps* would be soon established, and the young physicians departing from the college halls would not seek the advice of shopmen and others of similar ilk, in regard to the best methods to be employed to obtain a practice. If this course should ever be adopted, I shall then expect to see the profession rise above the level of laborers and shopmen, instead of occupying the lower plane. The Medical Record has already directed against this homicidal party one of the most potent agencies known to the present age. The medical press wields a power, in the profession, second to none other in the land. Therefore it is hoped that every reputable journal will soon join in this grand work of reformation. This field promises more, even in the way of saving human life and the relief of human suffering, than the much discussed topic of Koch's lymph.

X. Y. Z.

IS IT DANGEROUS TO MAKE LOCAL APPLICATIONS IN CHRONIC ENDOMETRITIS?

To the Editor of the Medical Record.

Sir: I have read with a great deal of interest the various discussions on the treatment of chronic endometritis by the gynecologists of to-day; and from what I can gather from them the majority condemn any local applications, such as carbolic acid, tincture of iodine, etc., to the endometrium for the cure of endometritis.

They not only condemn it, but say that many cases of pyo-salpingitis and other troubles arise from this treatment. The sound, too, has come to be a dangerous instrument, and carries death and destruction with it.

I have been treating this disease for a good many years with topical applications to the endometrium, and I have been so fortunate as not to produce the various troubles that I now see so often follow such a course of treatment. And not being able always to locate exactly the position of the uterus, I have not hesitated to use the sound without disastrous results following its introduction into the uterine cavity. I have had patients under treatment for this disease whose description of their condition, when they came, was pitiable to listen to. And those same patients have left me feeling like they were new beings, with a relish for life and its surroundings, and free from all uterine discharges and backaches.

I have had them in some instances to come thirty and forty miles on the railroad, and return the same day, after having an application made to the endometrium. This I do not think a safe course to pursue, and would never advise it. But my experience has taught me that there are uteri you can take liberties with. Some are excessively sensitive, and, with such, a powerful caustic application might light up an acute inflammation and produce a pyo-salpingitis and make an invalid for life unless the tubes were removed.

Have our women changed so much in twenty-five years that treatment which was considered safe and reliable at that time is now not only rash and dangerous but should be totally discarded? I have at the present time patients under treatment who tell me they have improved wonderfully and feel well, who were never free from aches and a tired feeling when they came to me for treatment. Can this be only their vivid imagination? And does it, too, arrest the leucorrhœa? Will it bring back ruddy cheeks with the glow of health? I have seen this produced in these patients, and I had attributed it to the local treatment, because in some instances I gave no constitutional treatment whatever.

I have a profound admiration for some of the gynecologists of to-day, and no one would give them more hearty applause for their brilliant achievements than I. In their skilled hands deeds have been accomplished that were undreamed of many years since. I honor them for the lives they have saved and are daily saving by their skill. But a fact established by a competent witness is not to be despised even in this day of great things, and there are many competent who will, I know, substantiate what I have said.

Yours truly,

W. H. Johnston, M.D.

Birmingham, Ala.

Persistent Reflux of Bile into the Stomach. From clinical observations on this disorder Dr. Weil has been led to formulate the following conclusions: 1. There exists a grave malady of the digestive organs, in which there occurs a permanent and abundant reflux of bile into the stomach. 2. This morbid symptom is essentially due to a deviation in the direction of the duodenum. This duodenal displacement is not dependent on any organic lesion, properly so-called. 3. Mechanical measures or surgical interference are necessary to re-establish the normal condition of things.—*Lyon Médical.*

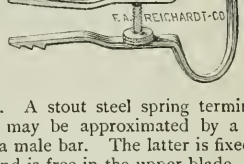
New Instruments.

A MODIFIED INTERDENTAL PRY.

By CHARLES A. POWERS, M.D.,

NEW YORK.

Three cases of fibrous anchylosis of the lower jaw, suitable for stretching, have been under my care during the past year, and in each I found it difficult to effect this by means of the ordinary oval specula, in which separation of the blades is effected by force applied through a ratchet or screw. Pressure thus exerted is inelastic, and it is difficult to finely adjust it. The accompanying cut illustrates a simple device which has proved very satisfactory



in my hands. A stout steel spring terminating in two blades which may be approximated by a female screw travelling on a male bar. The latter is fixed beneath the lower blade and is free in the upper blade. When introduced, closed, between the teeth, separation to any desired extent may be effected by unscrewing; the force thus exerted will be elastic and less painful than when the blades are directly screwed apart. I have found it useful to allow the patient to employ the instrument at home, several times daily, each time releasing the blades a trifle more than at the previous sitting.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 15, 1891, to February 21, 1891.

Byrne, Charles C., Lieutenant-Colonel and Surgeon. By direction of the Secretary of War, is relieved from duty at Fort Sam Houston, Tex., and will report in person to the Commanding General, Department of the Columbia, for duty as Medical Director of that Department, relieving Colonel Bernard J. D. Irwin, Surgeon. S. O. 36, par. 6, A. G. O., Washington, D. C., February 13, 1891.

Irwin, Bernard J. D., Colonel and Surgeon. By direction of the Secretary of War, on being relieved by Lieutenant-Colonel Byrne, will proceed, via San Francisco, Cal., to St. Louis, Mo., and report in person to the Commanding General, Department of the Missouri, for duty as Medical Director of that Department, relieving Colonel Charles Page, Assistant Surgeon-General. S. O. 36, par. 6, A. G. O., Washington, D. C., February 13, 1891.

Page, Charles, Colonel and Assistant Surgeon-General. By direction of the Secretary of War, on being relieved by Colonel Irwin, will report in person to the Commanding General, Division of the Atlantic, for duty as Medical Director of that Division. S. O. 36, par. 6, A. G. O., Washington, D. C., February 13, 1891.

The Moscow Pathological Institute has already received 10,000 roubles from the heirs of the late Dr. Kunin; 5,000 roubles from Baron L. Knoop, and 2,000 roubles from Messrs. Junker & Co., bankers, for the improvement of its scientific equipment.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 21, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	3
Scarlet fever	185	30
Cerebro-spinal meningitis	2	6
Measles	367	18
Diphtheria	115	30
Small-pox	2	0
Varicella	13	0
Pertussis	2	9
Croup	0	0
Mumps	0	0
Rötheln	0	0

New York's Insane: An Abstract of the Second Annual Report of the Commission in Lunacy.—The Second Annual Report of the New York State Commission in Lunacy has just been issued, and at this time, when the State care of the insane is so prominently before the people and the Legislature, it is an exceedingly interesting volume. It is a comprehensive review of the work done by the Commission, and its perusal will leave few disinterested opponents to either the Commission or State care of insane persons. On October 1, 1890, the whole number of committed and registered insane (the Commission deals with no other) was 16,002; the number of asylums, public and private, 30; the total cost of the asylums, together with grounds and equipments, up to October 1, 1890, was $16,291,600.37; the number of persons employed in the care of the insane, 2,707; the total receipts of the institutions for the past year, from all sources, were $3,157,000. The figures show the department to rival in importance the canals, schools, and State prisons. Nevertheless it is the least centralized as to government. At present the government is vested in boards of trustees of no universal size, they make separate reports to the Legislature, the State Commission and the State Board of Charities clash, and, in short, there is very little, if any, system. With such a state of affairs no intelligent line of policy or action can be followed. The Commission suggests two plans for a change: First, the adoption of a system similar to the one prevailing in the normal schools, viz., the appointment of local boards for each institution by the Commission, responsible to it for their action; or, secondly, the system that controls prisons and canals, through the assumption by the Commission of the general government of the institutions. If the present system should continue, the local boards should be smaller and of the same size; the members should serve a definite term and hold no other federal office; reports should be made to the Commission, which would make one general report to the Legislature; there should be a unification of salaries of officers and employees, unification of the grades and salaries of the physicians; receipts of State hospitals should be paid into the State treasury, and specific appropriations made therefrom; general supplies should be purchased upon contract. The Commission has already established a uniform method of bookkeeping, registration, keeping of histories, etc., and consequently, for the first time within the thirty years' existence of State institutions for the insane, statistics will be reliable and useful. Another good recommendation is the establishment of a pathological laboratory. In the judgment of the Commission greater attention should be paid to the study of the morbid anatomy and pathology of insanity than is now paid. There is abundant material which is not now utilized. Though a pathological laboratory was many years ago established in the Utica State Hospital, the report is authority for the statement that, as at present organized, it produces no results of scientific value in the line of original work. The Commission recommends that a pathological department be maintained at one of the State hospitals; that it be equipped with every necessary scientific appliance, and that the State provide such liberal compensation as will command the services of a pathologist of the highest scientific attainments, who should devote all his time to the work, and publish the results of his labors at stated intervals for the benefit of the State, in order that the State may have all the light which scientific research can throw upon the causation, development, and pathology of insanity.

The subject of the State care of the insane is exhaustively treated. The horrors and the abuses of the old system when "chronic" cases were turned over to poor-house care are shown up, and simply refute all opposition. No one is justified in terming a case of insanity chronic, with the idea that it is incurable, as there are recoveries after years have elapsed. The very word chronic, with its attendant pauper life, tended to prevent recovery. Dr. John P. Gray and most great authorities have been opposed to the theory of incurability. As the system of county care depended entirely upon the incurability of insanity, it was fallacious. As a rule, county insane were visited tri-weekly by untrained practitioners, there were no facilities for care or treatment, and consequently results were of necessity bad. The patients deserve better treatment, and now that the law for State care is passed, sufficient money for its enforcement should be appropriated. The Commission wants less than $500,000. An interesting portion of the report is that relative to the decrease of insanity in the State. Heretofore the statistics have shown an increase, but these figures were unreliable because of differences in methods of basing returns, and from the fact that former estimates were partially based on opinions of superintendents of the poor. The Commission, however, has established a system of registration whereby records of all commitments and discharges are kept in the offices of the Commission. Hence, time only is required for reliable statistics. These already show a decrease, or rather the amount of increase is declining. At present the registered insane are only about .00266 of one per cent. of the total population of the State. The report says: "This decrease can be accounted for largely by reason of the more intelligent, humane, and skilful treatment which has been furnished in recent years. Every year witnesses a greater number of the insane in proper quarters and under better medical supervision. If insanity is a disease that can be cured by treatment, and of this few pretend to entertain any doubt, then the better the treatment, within reasonable limits, the greater the number of cures. And, in view of all that has been said, the Commission desires to emphasize its opinion that by a continuation of the policy sought to be carried out by the last Legislature the proportion of the insane to the population can be very materially reduced—perhaps as much as twenty to twenty-five per cent. below what it is now." The average length of life of the insane is put at eight years by the report, a reduction from former estimates.

Reproduction of Bacteria.—It has been very reliably determined that bacteria, when placed in the best conditions for their activity, will double their number every hour. In the most favorable circumstances it will then be seen that a single bacterium will, in twenty-four hours, produce 16,777,220 of its kind. In forty-eight hours, from this single source, the number of bacteria would amount to 281,500,000,000, a quantity sufficient to fill a pint measure, all produced in this short time from a single micro organism measuring but $\frac{1}{15000}$ of an inch. Fortunately, these conditions do not often exist. The reproduction of bacteria is opposed by many kinds of forces, and they have a continual battle for existence. In regard to the disease-producing or pathogenic germs, it is important to understand what forces or agen-

cies will retard their multiplication or wholly destroy them. In emergencies chemistry is resorted to and antiseptics employed, but in the proper prevention of disease such emergencies should not be allowed to arise. Sunlight, pure air, and thorough cleanliness are natural enemies to disease germs. They cannot flourish where they have not their proper food, and that is found in dampness, darkness, mould, and filth. Keep the habitation flooded with sunshine and pure air, keep away all filth and dampness and the germs of disease will find no foothold, no nidus in which to breed or food on which to grow. Nature is struggling all the time to keep her domain healthful, and a fit habitation for man, but man shuts out the air and light, contaminates all things about him, and disease is the reward of his recklessness and neglect. There is more health in a sunbeam than in drugs, and more life in pure air than in the physician's skill. The sunlight may fade your parlor carpet, but better that than have disease fade your cheek. The wind may "tan" and "freckle" the face, but it is better tanned and freckled than thin and sallow. Help nature to keep your habitation healthful by allowing her forces an opportunity to operate. There is more health about you than disease. Health is man's natural condition. He has to violate some law before the penalty of disease is inflicted. He can place about him such conditions that disease-germs will invade his system, or he can live amid surroundings so pure that health will bless him both in his freedom from physical ills and in the sweet consciousness of right living.—*Sanitary News.*

"Tetanie" or Arthrogryposis.—The Vienna correspondent of the *Medical Press* writes that Dr. Chvostek read a paper on the relations of the acoustic nerve to cuticle resistance in "tetanie," or as Trousseau preferred to call it, "contracture des nourrices," from its frequency in pregnancy and lactation. The disease is characterized by painful contraction of a group of muscles supplied by a particular nerve—seldom the hips—having different periods of intermission, whose origin is central, though no pathological change can be demonstrated. He put great force on the characteristic symptoms being subjective, and thus belonging to the sensible nerve system. This knowledge of the disease he considered was due to Hoffmann's investigation, who proved conclusively that the sensory nerves, as well as the motor nerves, were hyperæsthesic, or easily irritated by the galvanic or Faradic current. He referred to seventeen cases he had examined in Kahler's klinik, where the hyperæsthesia was present, and disappeared as soon as the spasmodic attacks subsided. He next described the effects of the electric current on the organs of sense, referring more particularly to the acoustic nerve. In all the cases examined he had only fifteen per cent. that gave a normal reaction. There was not only this high percentage of hyperexcitability present, but it was accompanied with a peculiar sound sensation. Schlesinger asked which of Trousseau's phenomena were considered characteristic of tetany? His own opinion was that the facial symptoms were in no way a characteristic sign of the disease, but rather the early manifestations of tuberculosis. This led him to ask if tetany could be present without the cramp attacks, and he related a case in favor of the absence of cramp from a young woman who had paræsthesia and stiffness of the fingers for a year without the attacks, but every other symptom of tetany was present. These cases are not uncommon, as Frankel-Hochwarth has applied the term "tetanoid" to obviate the difficulty. Neusser related a case of tetany with a peculiar mixing of symptoms; hyperæmia of the optic papillæ, transitory and alternating swelling of the nasal muscles, laryngeal spasms, and finally polyuria. It is true there are cases of tetany where we can easily locate the disease to the medulla oblongata, but there are others with a psychological combination, frequently confirmed by the autopsy, in finding the brain hyperæmic, ecchymosed, as well as the meninges of the spinal cord, that would force us to the conclusion that the disease is a systemic one, and that its origin may be located in the spinal coverings, the terminal points of the central nerve system, or in the periphery of a nerve-trunk, as it occurs in tabes generally.

Cholera in Japan from 1884 to 1887.—Although no year since 1877 has been free from cholera, there has been considerable difference in the virulence of the disease. The year 1884 was characterized by the mildness of the form prevailing. The number of cases, too, were less than in the preceding year. This dreadful malady made its appearance at Nagasaki toward the end of July, 1885. It raged with great severity in different localities of Kyūshū for over a month, and then made its way eastward. Though suppressed for a time, it made its appearance again in 1886, when it assumed the form of a violent epidemic, spreading far and wide, reducing the country to a state of misery that had not been known since 1877. Such a degree of severity may be attributable to the development of the poisonous germs that lay dormant in the previous year. Subsequent to the first outbreak of cholera this year, the local authorities had been most punctual in inspecting travellers by land and sea, and had endeavored by every possible means to suppress the disease, but in spite of these efforts it spread over all parts of the empire. During the four years from 1884 to 1887, there were 171,879 cases of cholera and 118,809 deaths; 166,456 cases of enteric fever and 36,261 deaths; 11,041 cases of diphtheria and 5,600 deaths; 16.473 cases of typhus fever and 2,835 deaths; and 127.578 cases of small-pox and 32,382 deaths. The above statistics show that the cholera cases far exceed those from any other infectious or contagious disease.—*Abstract of Sanitary Reports*, vol. v., No. 35, 1890.

Sterilizing Milk by Peroxide of Hydrogen.—Peroxide of hydrogen has been used to disinfect water. Dr. Heidenhain says that it may also be useful for sterilizing milk, although he is not able to say as yet how the digestibility of milk so treated will be affected. He finds that children take it readily, and that the peroxide, mixed in the proportion of five or six tablespoonfuls to one quart of milk, does not cause the milk to curdle or to become sour, even when it is left in a room at summer temperature for forty-eight hours, the slight acid reaction with litmus paper being due to the action of the disinfecting material and not to the production of lactic acid. The cream that rises is so sweet that butter cannot be made from it for a very considerable length of time.—*Centralblatt für Bakteriologie.*

Religious Advertising of Quack Remedies.—Some years ago the *Northwestern Christian Advocate*, a religious weekly paper, in obedience to public sentiment, systematically excluded so-called patent medicine advertisements from its columns. This was done with considerable ostentation, the editor calling attention to the matter of financial sacrifice involved, and for this reason urging an increased subscription from the church. It is to be regretted that within the last few months, however, this eminent church organ has returned to its bad habits, and is printing advertisements of patent medicines without stint. This action is made more noticeable by the appearance lately in the *Advocate* of two most excellent articles upon the subject of higher medical education. The argument was that a rigid examination should be the test of fitness to practise medicine. Have the people whose wares his paper is trying to foist upon the public passed this rigid examination? Can they show any reason that would satisfy a much less exacting person than the *Advocate* editor would have us believe he is, why they should not be restrained from hawking their nostrums through the newspapers? These are pertinent questions.

Two Cases of Death from Hydrophobia have recently been reported; one occurred in Connecticut, and one in Indiana.

INOCULATIONS WITH PROFESSOR KOCH'S "TUBERCULIN."[1]

By A. JACOBI, M.D.,

LATE PRESIDENT OF THE NEW YORK ACADEMY OF MEDICINE; CLINICAL PROFESSOR IN THE COLLEGE OF PHYSICIANS AND SURGEONS, ETC.

(Continued from page 254.)

A CHILD nineteen and one half months of age was inoculated in the very last stage of tubercular meningitis on December 12th, with one half of a milligramme, on the 13th, with one milligramme of "tuberculin." There were no changes in her hopeless condition attributable to the injection.

E. R——, boy aged eleven, admitted October 23d, with tubercular peritonitis and ascites. Disease began six months previously, with frequent but moderate pain, but no fever or rigor. Convolutions of intestines are easily distinguished (adhesions). Constipation. Never a temperature beyond 99.5° F., never one below 98° F., until December 26th, when the first milligramme was injected at 6 P.M. Temperature at 9 P.M was 97.8° F.; pulse 80. At 12 M. on the 27th, 97° F.; pulse 88. At 3 A.M., 101° F.; pulse 100. At 6 A.M., 102° F.; pulse 120. At 9 A.M., 103.3° F.; pulse 114. At 12 M., 101.6° F.; pulse 116. At 3 P.M., 101.8° F.; pulse 112. At 6 P.M., 102.2° F.; pulse 116. At 9 P.M., 100° F.; pulse, 108.

The first temperature of 99° F. was reached at 3 A.M. on the 28th, at noon it was again 97° F., still with a pulse of 106. Second inoculation of 1 milligr. at 6 P.M.; only rise (101.2° F.) at 9 P.M. On the 29th at 6 P.M. 2 milligr., also on the 30th. No rise, several times 97° F. On January 2d, 3 milligr. at 6 P.M. At 9 and 12 P.M., and at 3 and 6 A.M. on January 4th the temperatures were 97.8° F., 97.4° F., 97-98° F. No rise.

January 4th, 6 P.M., injection of 3 milligr. Temperature at 9 P.M., 96.5° F.; at 12 M., 97° F. 3 A.M. of the 5th 99.4° F.; 6 A.M., 100.3° F.; the only rise. That night temperature for many hours was 97°, 96.2°, 96.9° F.

January 6th at 6 P.M., with a temperature of 97.3° F., 5 milligr. were inoculated. For twelve hours afterward temperature was between 97° F. and 96.2° F. No rise except once, to 100° F., at midnight of January 8th. This was the only time when the pulse was as low as 70.

On January 10th 10 milligr. were injected, temperature sank again to near 96° F., as heretofore, rose and fell, once at midnight of the 13th to 95.8° F., with a pulse of 62.

On January 16th with a temperature of 97.2° F., at 6 P.M., 10 milligr. were injected. The first effect was again a fall to 97.8° F., and 97.2° F.; then, at 3 A.M., a rise to 102° F. and pulse, 116. At 6 A.M., 99.4° F.; pulse, 108. At 9. A.M., 101.2° F.; pulse, 120. At 12 M., 102° F.; pulse, 122. At 3 P.M., 99.6° F.; pulse, 108. At 6 P.M., 100.6° F.; pulse, 130. After that the temperature fell, with the exception of midnight the 19th, when it was once 101° F. It then fell a few hours, rose again in the morning hours of the 20th and remained twelve hours from 100.2° F., to 101.7° F.

On the 23d, about noon, I made an inoculation of 20 milligr. At 6 P.M temperature was 104.4° F., with a pulse of 112. All next day it remained above 100° F. He left the hospital on the 26th. During all these weeks he felt very comfortable except when under the influence of high temperatures, and his general condition improved. Still, it had improved before the lymph treatment was begun; his strength increasing and ascites diminishing.

M. C——, aged five years and six months. Tubercular peritonitis, ascites. Was said to have been sick a week with tumid abdomen and loss of appetite. For some days after admission the highest afternoon temperature was 100.5° F., morning temperature as low as 98.4° F. First inoculation of half a milligramme at 8.45 P.M. on January 3d. Within five hours the temperature was 103.2° F.; pulse, 148; respiration, 30. The temperature rose to 104.5° F., and the accompanying symptoms became so alarming that phenacetin and brandy were administered several times. Not before the 6th was the temperature again below 100° F. After the next inoculation reactions would always show themselves, but the effect grew less gradually, though the doses were increased from one half to 2 milligr. Very suddenly and unexpectedly, eighteen days after the treatment was begun, the temperature rose again to 104.6° F., with corresponding rise of both pulse and respiration. No particular change in the three weeks she was in the hospital.

The following are a number of cases of pulmonary tuberculosis in different stages:

Mrs. R——, twenty-five years of age. Admitted December 17th. Singing lessons from seventh to seventeenth year; hæmoptysis at seventeen; acute pulmonary complaint two years ago and a year ago. For eight years occasional dyspnœa, cough, and expectoration. Left upper lobe, extensive dulness and coarse respiration; right lower lobe, local dulness and rhonchi. Bacilli.

December 18th. Injection of 1 milligr. at 6 P.M.

December 19th. Slight rigor in afternoon, with temperature of 101.3° F., and perspiration; 9 P.M., 102° F. (highest temperature). Pain in site of inoculation. First normal temperature returned December 21st at 9 A.M. At 12 M., 1 milligr. After twenty-four hours, December 22d, 9 A.M., 100° F. Spleen enlarged. Highest temperature at 6 P.M.; at 9 P.M., below 100° F. Headache all day. December 23d some cough. At 12 M. temperature 100.2° F.; 6 P.M., 100.6° F.

Injection of 2 milligr. at 7 P.M. on December 24th; 2 milligr. the 26th; 3 milligr. the 29th; 4 milligr. the 31st; also the 2d, 4th, and 6th of January. The highest temperature on the 25th was 101.4 F.; the 27th, 102° F.; the 30th, 101.2° F.; January 1st, 100.7° F.; January 3d 103° F; the 5th, 102.4 F.; the 7th, 99.4° F. These temperatures were reached in from sixteen to twenty-two hours after inoculation. During all this period her general discomfort, local pain, cough, and perspiration became lessened.

Inoculations were made on the 8th, 6 milligr.; the 9th, 7 milligr.; the 11th, 8 milligr.; the 12th, 9 milligr.; the 14th, 10 milligr; the 16th, 11 milligr.; the 17th, 13 milligr.; the 18th, 13 milligr.; the 21st, 23d, and 24th, each 15 milligr.; the 25th, 20 milligr.; and the 26th, 25 milligr. During all this time her general condition improved; her temperature was mostly between 98.5° and 99.5° F., and seldom rose to 100.2° F.

John H——, aged twenty-eight, admitted January 15th. Tuberculosis pulmonalis et laryngis. Family history of

[1] Read before the Medical Society of the State of New York, February 4, 1891.

phthisis, of which a brother and a sister have died. Hoarseness, dry throat, and occasional hæmoptysis more than two years ago. Permanently sick for a year, cough, some expectoration in the morning. Both increased three weeks ago. No pain, fever, or night-sweat. Short breath on exertion. Condition fair. Some retraction of left supra- and sub-clavicular region, dulness, crepitant râles down to third rib; posteriorly the same. About the middle of thorax some bronchial or prolonged expiration, a similar condition on the right side on percussion and auscultation.

Inoculations on January 15th, of 1 milligr.; January 16th of 2 milligr.; 17th of 3 milligr.; 18th of 4 milligr.; 20th of 6 milligr. had no visible effect whatsoever, the rectal temperature remaining at 99.6° F.

On the 21st, 10 milligr. were injected, with the result of raising the temperature to 103° F. within five hours and producing much cough. On the 25th, 5 milligr. were injected, the 25th, 10 milligr.; the 26th, 15 milligr. with no response on the part of temperature. It is probable that the dose of 10 milligr., if it had been the first, would have had the same result, and that this effect would have justly been claimed as pathognomonic for tuberculosis; though a later dose of 1½ centigr. did not in the least show the same effect. Six milligrammes, however, elicited no temperature response; while other cases respond to smaller doses so readily that, if larger doses were given to them, danger might be incurred. Thus for instance:

E. V——, aged twenty-five, with undoubted pulmonary tuberculosis, dulness, bronchial respiration, purulent expectoration, bacilli, and night-sweats had 1 milligr. injected on January 25th, with no result; another on January 26th, with an increase in temperature, which reached its maximum, 101.8° F., after fifteen hours. In this case it is remarkable that the second effective dose was not larger than the first which refused its effect. Still, it is possible that the reaction following the first inoculation occurred only after more than a day after—in accordance with some other observation of the same kind.

G. P——, aged thirty-two, admitted December 11th, with the diagnosis of incipient tuberculosis of the lungs. Had dulness and crepitant râles over clavicle and supra-scapular region of the right side. Respiration over fossa supraspinata diminished. Sputum not copious, but contains bacilli. Weight, 127 pounds.

Inoculation of 2 milligr. on December 12th; 3 milligr. the 13th; 4 milligr. the 14th; 4 milligr. the 15th. Temperature rose to 101.6° F. in twenty-two hours. Injection of 5 milligr. on the 17th with no visible effect. Patient weighs 137 pounds on the 19th. Injection of 6 milligr. on the 20th was followed by a temperature of 102.4° F. on the 21st; 6 milligr. on the 23d by 101° on the 24th; 7 milligr. on the 25th by 101.8° on the 26th; 7 milligr. on the 28th by 101.2° on the 29th; 9 milligr. on the 30th by 101° on the 31st.

On January 1st no inoculation, and no temperature above 100° F. (This but once.)

On the 2d of January a new start was taken with 2 milligr., and thirteen inoculations were made up to the 19th, when the treatment was discontinued. Meanwhile the doses had been gradually increased to 10 milligr. But twice was there a temperature as high as 100° F. during that time. The general condition improved from day to day, and about the end of the month the patient was discharged in good health, without cough, and without any râles and any dulness. Recovery (?).

J. W. B——, aged twenty-five, tuberculosis pulmonum. Father died of consumption; patient had symptoms these several years. Bronchial respiration over upper lobes both right and left posteriorly, also slightly over the left lower lobe; loud bronchial respiration over left upper lobe in front; moderate dulness over total right side. From December 20th to the end of January, when she left, twenty-two inoculations were made, ranging from 1 to 15 milligr., the latter dose being given four times. The first rise of temperature occurred on December 26th, after a dose of 3 milligr. on the 25th; the first temperature of 102° F. was reached January 10th after a dose of 7 milligr. had been given twelve hours previously. The same was reached again on January 26th, sixteen hours after the fourth dose of 15 milligr. (the first on January 20th) had been administered; also on January 27th, sixteen hours after 15 milligr. on the 26th. It must be added, however, that after the temperature had come down to 98° F. in the early morning hours of the 28th, it rose to 102.9° F. in the afternoon. Thus it remains doubtful whether the higher temperatures of the afternoon (mostly sixteen hours after the inoculation) were due to the injection or to the pulmonary process. For when the patient left about the end of January, her claim of feeling improved was not justified by either increase of weight or any appreciable change in her lungs.

M. P——, aged twenty-one, admitted December 12th. Tuberculosis pulmonum et laryngis. Color of vocal cords grayish red; edges eroded, fossæ Morgagni ulcerated, posterior wall of larynx slightly thickened. Extensive rhonchi over chest, dulness below right clavicle. Bacilli numerous. Inoculations were made, December 13th, 1 milligr.; 14th, 2 milligr.; 16th and 18th, 5 milligr. each; 21st 6 milligr.; 23d, 25th and 28th, 5 milligr. each. Reactions were quite marked after the first inoculation, though they required nearly a day for their maximum. Cough, expectoration, and temperature increased, larynx became sensitive. At no time was the temperature anything like normal. Examination on December 26th revealed: No change in larynx, complete aphonia; over left upper lobe dulness, coarse respiration, moist and sibilant râles, over apex cavernous breathing; over almost the whole right lung bronchial respiration, and moist and sibilant râles. As his condition was so much impaired, I hesitated giving the same doses, being under the impression that possibly the injection might add to his high temperatures and the extension of the morbid process. Therefore after waiting five days, during which the general condition and the temperature of the patient showed no difference from former observations, I injected 2 milligr. on January 2d. The last injection of this new series, which consisted of fourteen inoculations of from 2 to 5 milligr. was made on January 20th. No perceptible effect. Death on January 25th.

M. A——, aged nineteen, admitted January 7th. Pulmonary tuberculosis. Began with a pleurisy, October, 1889. Languor, cough, fever, night-sweats last spring, expectoration with bacilli, but seldom in bed. Right upper lobe has prolonged expiration and sibilant râles. Left, normal. Posteriorly, over right apex, wheezing and moist râles. Some dulness over right upper lobe, anteriorly.

Inoculations were begun January 9th, from the 9th to the 19th. They were repeated daily, commencing with 1 milligr., and gradually rising to 9 milligr. From January 21st to 29th eight inoculations were made, each of 10 milligr. During all this time no improvement took place; she coughed but little, with exceptions, perspired, felt often languid, expectorated some, slept well most of the time. During the first week (sixth day) the temperature reached 102° F.; but once, toward the end of the second week, it reached 102.5° F., touched 104.5° F. several times in the third, and more in the fourth week. Toward the end of the month the temperature fell below 103° F. Meanwhile, though the patient's râles would increase from time to time, the dulness did not extend; still, her general and local condition did not improve.

A. H——, aged twenty-one, admitted December 29th; tuberculosis pulmonum. Had pneumonia a year ago; coughed almost all the time since with the exception of some months passed in the mountains. Dulness over both apices (mainly left), both anteriorly and posteriorly. Rhonchi over both upper lobes, in some places during cough only.

Inoculations: December 31st, ½ milligr.; January 1st,

1 milligr.; January 3d to 7th, four inoculations of 2 milligr. each; January 9th to 25th, a daily dose of 3 milligr., with the exception of the 14th, 19th, and 22d; January 26th, 4 milligr.; 27th and 28th, 5 milligr. each; 29th, 6 milligr.; 30th, 7 milligr.; 31st, 8 milligr. After the smallest doses the temperature would rise, sleep was restless, there were headaches and mild chills, also much perspiration, also palpitation. The temperatures till January 22d varied from 101° to 103.5° F.; in very rare instances only would they fall below 100° F. In the last week of the month, however, most observations showed temperatures below 100° F., many below 99° F., very few as high as 101° F. About that time her general condition, which had not been good at all, improved very much indeed.

I——, a girl aged five, with undoubted pulmonary tuberculosis, slight dulness over left lung both anteriorly and posteriorly, and higher pitch in right side than left, but no râles, had her first inoculation of 1 milligr. on January 6th. The case is remarkable for its punctual reactions. Within four hours, once after two, the temperature would rise without affecting either pulse or respiration after the first two injections. Only with the third, and every subsequent injection, both pulse and respiration rose correspondingly. The reactions lasted about twenty-two hours, a little less than one-half of this time being spent on the rise. Respiration, with a single exception, returned more readily to the normal than the pulse, which remained accelerated for some time. Still, when a sufficient time was afforded, temperature, pulse, and respiration returned to the original condition previous to any inoculations. Not improved in three weeks.

S. S——, aged thirty two, pulmonary tuberculosis, with infiltration of both upper lobes. The first injection of 1 milligr. appeared to have but little effect, the third of 3 milligr. given two days afterward increased his temperature within six hours. The maximum was 101.8° F., and was reached twenty-four hours after. Normal temperature on the following day (January 14th). On the 15th 3 milligrs. with rise of temperature within twelve hours; maximum of 102.6° F. within eighteen hours; at the same time prespiration, cough, great discomfort. On the 18th 3 milligrs. were again given without any such effect. Five milligrs. on the 20th increased the temperature within six hours, to a maximum of 103.9° F. within nine hours. The same dose on the 23d had no similar effect. But when given on the 25th it had again the effect of raising the temperature within seven hours, with a maximum of 103.8° F. within nineteen hours. It appears, therefore, that the same dose may lose its effect, and recover it at a later time, the intervals between the several administrations being the same, viz., two days.

F. T——, aged thirty-six. Pulmonary tuberculosis. Had fifteen injections from December 28th to January 31st, in doses of from one to eight milligrammes, with but little reaction and little effect. The smaller doses appeared to prepare the patient for readily tolerating the larger ones.

J. F. L——, aged thirty-nine. Pulmonary tuberculosis. Had a pneumonia nearly two years ago, and never lost his dyspnœa. For five months past, cough, expectoration, emaciation, night-sweats, bacilli. Over upper halves of both upper lobes, dulness, and crepitant râles. Thirteen inoculations between December 17th and January 6th, amounting to from one to twenty milligrammes. The latter dose was repeated on the 16th and the 20th, a few days after he left the hospital. The brief observations permitted resulted in the following: The third inoculation (first of 3 milligr.) was the first that raised the temperature to 102.8° F. at 9 A.M. and 102.5° F. at 12 M., fourteen and seventeen hours after the inoculation. Nearly the same temperature was reached three and six hours after the next inoculation of 5 milligr. It was never reached again, either spontaneously or after increased doses. Indeed there appeared a gradual downward tendency from day to day. The general condition certainly improved, and he gained a few pounds.

A. B——, aged thirty-three; admitted November 25th. Pulmonary tuberculosis. For a year and a half past, cough, four attacks of hæmoptysis, expectoration, night-sweats, emaciation, hoarseness. Bacilli. Family history negative. Supra- and infra-clavicular regions retracted. Dulness over both apices, also diminished respiration and some rhonchi. Over right lower lobe, posteriorly, dulness and bronchial respiration. During December, fifteen injections of from 1 to 10 milligr.; in January, seventeen of from 2 to 50 milligr. After the first inoculation the patient coughed much, both cough and expectoration grew less after the second, and remained so. At no time was there a temperature which had to be attributed to the action of the lymph; it seldom reached 101° F., then only in the afternoons (about a day after the injection) and for a short time. Within a week the patient felt better. Still, the examination of his chest made on December 26th revealed no changes except the disappearance of the rhonchi. During January, temperature almost normal; but little cough and expectoration. Increase of weight in one month, nine pounds. General improvement.

A. H——, aged thirty-nine, admitted December 4th with dulness over both apices and crepitant râles, and bronchophony over right apex. Bacilli. From December 13th to the end of the month thirteen injections were made of from 1 to 10 milligr. During the course of January sixteen injections were made, from 2 with rapid increases to 60 milligr. The first injection of 1 milligr. raised the temperatnre of 98.5° F. to 105° F. within an hour and a half, with intense perspiration, followed by a rapid fall afterward to 99° F. Maximum temperature in the afternoon of the 12th, 101.7° F.; of the 13th, 101.2° F. At that time 3 milligr. were injected, with no increase of temperature or any other signs of reaction. No such temperature was ever reached again, and the patient felt more comfortable from day to day. Still, the physical condition of December 26th revealed dulness posteriorly over left upper lobe, with considerably increased voice. On the right side bronchophony posteriorly over upper lobe, dulness over the two upper lobes. Temperature remained normal throughout January, weight increased by twelve pounds, cough became less, also expectoration, crepitant râles disappeared, dulness remained. Great improvement in the general condition.

In some cases of tuberculosis small doses of the lymph appear to reduce the temperature without giving rise to any other symptoms except the sensation of comfort. Patients will apparently not react on the administration of 1 milligr., then the dose is increased from day to day, slowly; the later doses will not affect the system any more than the first; indeed, 10 milligr. the tenth day is attended with the same lack of consequences as 1 milligr. given the first day, in accordance with the fact that when a serious reaction is experienced after a single milligramme has been administered, very much larger doses are soon required to accomplish the same end.

A lady, aged thirty-five, Mrs. M——, mother of a number of children, one of whom died a few years ago of miliary tuberculosis, had tuberculosis of the lungs and abdominal lymph-bodies, probably also the peritoneum, these ten years. The abdominal symptoms were very much improved compared with what they were a few years ago. But for years she has expectorated, coughed, was emaciated, formed large cavities in both apices, both of which have diminished in size for a year past, has had numerous attacks of pleuritis and pneumonia, and brings up bacilli in almost every sputum. Besides the extensive cavities she has large areas of dulness and coarse respiration, besides all kinds of rhonchi. Lately she had a severe pneumonia of which she got fairly well. Still, she went on with her old symptoms, and high fever, which required repeated large doses of digitalia and antipyrin.

The first milligramme was injected January 25th while she had a temperature of 101.8 F., which fell as low as 99° F. January 26th it rose in the morning to 100.4° F.

Injection of 2 milligr. at that time. Temperature sank to 98° F. Next morning again 100.4° F. and 3 milligr. Again 100.4° F. and 4 milligr. on the 28th; on the 29th the same and 5 milligr.; on the 30th the same and 6 milligr. in the afternoon. For the first time this week she had a temperature of 100 8° F. in the night through the course of a few hours. The following morning, January 31st, temperature below 100° F.; 8 milligr. at noon. First elevation twenty-four hours after, on February 1st, 100.5° F., rose to 100.8° F., was 100° F. again at 6 P.M., and fell below. Through all this week there was less cough, less expectoration, less perspiration, more appetite and comfort, in spite of the three daily doses of medicine being reduced to one, and that one reduced in size.[1]

A similar observation was made in E. L——, aged nineteen, admitted December 25th. He had been sick in bed seven weeks, his condition had been carefully watched, and temperatures recorded. They were seldom as low as 101.5° F., mostly from 102° F. to 104.5° F., and sometimes higher. Has been reduced to 102½ pounds. Dulness and fine rhonchi, crepitant and sibilant over the left upper lobe, also bronchophony. Over the right upper lobe posteriorly, over large area, dulness, rhonchi crepitant and sibilant, and bronchophony; anteriorly, dulness, bronchial and cavernous breathing, and rhonchi. Bacilli. Had twenty-nine inoculations from December 25th to February 27th, the latter day 5 milligr.; all the rest from 1 to 4 milligr., with a slow increase. On December 27th, the first temperature of 100° F. was reached, the lowest in seven weeks; 99.8° F. on the 28th; 99.4° F. on January 2d; 99° F. on the 3d, 9th and 10th; 98.4° F. on the 14th; 98.6° F. on the 22d. All this occurred while his local symptoms did *not improve*. On contrary his cavity in the right apex is increasing in size, expectoration still copious and bacillary, though more fluid. Lately he has again temperatures of 102° F., and even 103° F., which cannot be taken as the result of lymph-action, but are undoubtedly the outcome of the destructive process, which is not checked. This case shows that the patient may feel very much improved without an actual change in his pathological condition, even while getting worse.[2]

E. A. B— , aged thirty-three, admitted January 3d. Since January, 1890, loss of weight (now 152½ pounds) and strength. For some months past hoarseness. The posterior wall of larynx hyperæmic; left vocal cord unhealthy, will be described later on. No night-sweats. To those who saw him before admission, he looked feverish. Being a doctor, he never took his temperature. Right lung over clavicle: Dulness and during a cough crepitant râles; posteriorly crepitant râles over the whole upper lobe. Left lung: Dulness trifling over clavicle, slightly coarse respiration. Between January 3d and 13th, ten inoculations were made, from 1 to 10 milligr., increasing by 1 milligr. from day to day; on the 14th, 10 milligr.; 16th 17th, 18th, 15 milligr.; 20th, 20 milligr. The injections were made about 7 P.M., the only temperature above 100° F. would be found in the afternoons, the highest ever noticed being 100.8° F., and that only once; low temperatures were observed, down to 98.2° F. On several days the temperatures never reached 100° F. During all this period no bacilli were found, and therefore I stopped the inoculations on January 20th, when the last one of 20 milligr. was made. On that day the highest temperature was 100° F.; on the 21st, 100.1° F.; a single time, the 22d, 100° F.; a few evening hours, the 23d, over 100.8° F. very exceptionally. On that day the sputum, which was always scanty, was again examined, and a large number of bacilli found, many of them broken up as described in *Deutsche Med. Wochenschrift*, No. 46. At 11.10 A.M. 25 milligr. were injected. At midnight the temperature was far below 100° F., and remained so (down to 98 6° F.) until 9 P.M. on the 24th—indeed the first day when there was no increase in the afternoon. On the 24th, at 8.30 P.M., 30 milligr. From 6 A.M. to 9 P.M. the 25th, temperature from 100° to 100.7° F., the first indications of a response such as every healthy person would show. The same occurred after 40 milligr., which were injected at 8.25 P.M., the 25th. Temperature rose, 9 A.M. on the 26th, to 100.3° F., reached 101.4° F. at noon, and was below 100° F. late in the evening. Two days later 60 milligr. were injected with no more marked result.

That case shows conclusively that the lymph did not cause any reaction pointing to the presence of tuberculosis when injected in doses varying from 1 to 60 milligr. The slight responses met with in these high doses may be found in the healthy. Besides, the case is noticeable as one of those in which bacilli may not be found for some time and still be present. The question whether the bacilli were freed by the action of the lymph must be answered in the negative; for there were no marked rhonchi during the period of inoculations, and we have a right to conclude that the tissue surrounding the bacilli nests was not congested and softened by the action of the lymph.

This case is interesting from an additional point of view. On January 8th there was a flat, slightly granulating ulceration of the posterior half of the left vocal cord, paresis of the adductors, the whole mucous membrane quite pale. On the 22d two-thirds of the ulceration had closed, paralytic symptoms improved, the mucous membrane just as pale as before. There was no local reaction at any time after an administration of lymph, all of which shows that not only the general but also the local reaction may fail, but still a local improvement may take place.

In the case of H. C——, aged nineteen, admitted December 15th, similar observations were made, though not so conclusive for the following reason. He had been sick with cough, purulent and bloody expectoration nine months, was emaciated, feeble, and feverish. There were dulness, crepitant and sibilant râles, coarse respiration, bronchial respiration over both upper lobes. Bacilli copious. The first inoculation of 1 milligr. was made on the 15th, the 9th of 9 milligr. on the 25th, with the result of reducing his temperature. He entered with temperature 103° F., which he did not reach again. Indeed, most of his temperatures were below 100° F., once 98.6° F., reached 101° F. but seldom, and were 101.7° F. but twice, and for a short time only. Two days after the first inoculation he slept well in the night, perspired less, cough but trifling, feels comfortable. But after the sixth injection, on the 20th (7 milligr.), cervical and axillary glands and a long string of lymph bodies were found swollen and painful on both sides of chest. On the 26th I stopped the inoculations because those lymphatic glands were increasing considerably, and in spite of the lowered temperatures the general condition of the patient was bad. On the first day when no injection was made, his temperature rose to 102.5° F., the next to 102.4° F., the third, 103.1° F.; the fourth, 104° F.; the fifth, 103.7° F., with general malaise, vomiting, and some albuminuria; the sixth, 103.6° F.; the seventh only 101.7° F.; the eighth, 102.1° F. But there were some temperatures below 100° F., and his general condition was better. the glands also smaller; thus I resolved to keep him as I thought under the constant influence of the powerful remedy by giving a daily dose of only 2 milligr.; this has been repeated sixteen times up to January 19th. When the first 2 milligr. were given there was no longer any albumin in the urine. The temperature decreased gradually, the periods of less than 100° F. became longer,

[1] Four weeks have elapsed since. There has been some afternoon rise of temperature every day which could be controlled by a daily dose of digitalin and antipyrin. Meanwhile daily doses of tuberculin have been injected; they reach at present a decigramme without the slightest feverish reaction. The cough is reduced to one-fifth of what it was, expectoration is much less and easier, the râles are audible on one side only, large areas have their vesicular respiration restored to them, and the weight of the body has increased by more than six pounds.

[2] In the course of the last few weeks, the general condition of the patient improved sufficiently to enable him to take long walks.

on the 8th it did not rise at all beyond 101° F., and did not reach this figure at all between the 9th and 14th. On the 19th, when no inoculation was made, 102.1° F. was again reached through five or six evening hours. His general condition is not improved; has left for the South.

E. S——, aged thirty two, admitted December 16th, with the diagnosis of tuberculosis pulmonum. Bacilli have never been found, there being very little sputum. But has coughed these two years, had night-sweats, and some fever these four weeks. No history of tuberculosis in the family. On the right side dulness and fine crepitant râles over the clavicle, also below. Posteriorly the same. Over the lower right lobe diminished respiratory murmur and some dulness. On the left side, above and below the clavicle and in the supraspinal region, some crepitant fine râles during cough. This patient proved peculiarly immune against the effect of the lymph. He entered with a temperature of 101° F., and over, but never reached it again, seldom 100° F., was more frequently 98° F. than 99° F., and reached 97.2° F., lymph or no lymph. On December 1st, 1 milligr., and further on 2, 3, 5, 6, 10 (on the 30th), again on January 3d, 20 on the 8th, 25 on the 10th, 30 on the 14th, 40 on the 16th, 20 on the 23d and 25th; 50 on the 26th, 60 on the 27th, 70 on the 29th, 80 on the 30th. The doses were more than large enough to affect a healthy person. If it were not for the negative result of the search for bacilli, there would be no doubt in regard to the diagnosis. I do not feel, however, that I have a right to deny the presence of tuberculosis in the presence of all symptoms except bacilli. I have spoken of a case in which a two weeks' search for bacilli was in vain, and still they were present. Here, then, is an individual who in that condition is not affected by 360 milligr. administered within a week. Are we to call this absence of an effect the result of an idiosyncrasy? Though that term does not mean much and be only an expression of convenience, it shows that there is an occasional person that is not affected by a reasonably large dose of the lymph.

The condition of the patient is very much improved. Dulness has disappeared and there are no rhonchi. Evidently the pulmonary tissue has expanded, and the secretion stopped entirely. Improved, perhaps well.

Conclusions.—After an inoculation of tuberculous patients with tuberculin the temperature of the body would rise in from two to twenty-eight hours. Or it would not be influenced at all, in a few cases. Or it would fall first and then rise some. Sometimes it would rise, then fall and again rise. Still the rise is the usual occurrence. The descent from the maximum would in most cases take a longer time than the ascent. Unexpected rises of temperature were occasionally met with in inoculation of persons not tubercular. Perhaps there are other conditions besides tuberculosis in which tuberculin has the same effect. It is therefore not absolutely reliable in ferreting concealed tuberculosis. As a means of diagnosis it is not positively infallible. The doses required to obtain a reaction would vary considerably. Some patients would respond readily to a milligramme, some demanded ten times that amount. Children required relatively large doses, except the cases of tubercular peritonitis. One of them, at one time, after having shown high temperatures following previous inoculations, had a rectal temperature of 95.8° F., with a pulse of 62. The nature of the cases—whether bone, gland, skin, or lung—did not influence the effect of the doses. Lupus and pulmonary tuberculosis would be influenced by very small, or sometimes by large doses only. Therefore it is not safe to begin anywhere with 10 milligr., as has been advised, particularly as possibly the reaction may be retarded, and a second inoculation may have a cumulative effect. The therapeutic effect did not appear to depend on the energy of the reaction; on the contrary, some of the most favorable cases were those in which no, or very little increase of temperature was observed; while others, which exhibited high fever, and other symptoms of reaction, were endangered by dyspnœa, rhonchi, and the progress of local disturbance in the lungs. It seems advisable to begin with small doses in every case, and rather avoid than covet striking effects. At all events it is impossible to predict or calculate the effect of the remedy. Every case appears to require its own tentative treatment.

Other results of the inoculations were changes in pulse and respiration. In some these would correspond with the rise of temperature; in a few they would not be influenced. Sometimes the pulse, other times respiration would be more readily affected. The comfort or discomfort of the patient would not always be in accordance with the variations of temperature, pulse, or respiration. The site of the induration would sometimes smart, and flush after a while; indurations there were but few, abscesses none, local erythema extending beyond the site of injection a few, general eruption but one. No erysipelas. We have observed pain in the diseased part, in other limbs, swelling of glands sometimes in distant parts, perspiration, headache, rigors, languor, insomnia, palpitations, angina pectoris, nausea, increase of appetite, very slight jaundice, albuminuria in a few cases, increase of cough, diminution of cough, dyspnœa, rhonchi on expected and unexpected places, new regions of dulness, more expectoration—mostly in the beginning of treatment, change of its purulent into mucous character, increase or mostly decrease of secretion from accessible tuberculous parts, swelling of spleen and a peculiar form of glossitis in a few cases.

The results of, or events after, a protracted course of inoculations, may briefly be summed up as follows:

Tuberculosis of right knee. No change.

Dorsal spondylitis. No change.

Tubercular abscess in right inguinal region. No improvement.

Tubercular disease of right hip. No improvement.

Tuberculosis of right knee. No improvement.

Tuberculosis of right elbow. No improvement.

Tubercular ankle-joint, fistula. No improvement (in sixteen days).

Tubercular knee-joint. Death from miliary acute tuberculosis.

Caries of vertebræ and ribs. No improvement.

Cold abscess from right sacro-iliac synchondrosis. Slight improvement.

Tuberculosis of left tibio-tarsal articulation. Improvement.

Cutaneous tuberculosis. Great improvement.

Lupus vulgaris of nose and lip. Great improvement.

Epithelioma of right temple and face. No improvement.

Epithelioma of left temple and eyelid. No improvement.

Tubercular meningitis, almost moribund. No change.

Tubercular peritonitis. Two cases. Not influenced.

Pulmonary tuberculosis. Five cases. Improved. One of them relapsed and got worse.

Pulmonary tuberculosis. Four cases. Much improved.

Pulmonary tuberculosis. Two cases. Disappearance of local symptoms. Recovery. (Bacilli found in one.)

Pulmonary tuberculosis. Four cases. Not improved. Laryngeal tuberculosis in one of these much improved.

Pulmonary tuberculosis. One case. Died. Laryngeal ulcerations much improved.

I repeat: Of eleven cases of tuberculosis of bones and joints, eight were not improved, one died, two were improved.

Two cases of epithelioma not improved.

Two cases of cutaneous tuberculosis (one lupus) greatly improved.

Tubercular meningitis and peritonitis not influenced.

Of sixteen cases of pulmonary tuberculosis one died, four were not improved, five were improved, four were much improved, two recovered, even with disappearance of local pulmonary changes.

The two cases complicated with laryngeal tuberculosis did not thrive. One was not improved, one died. But in either the laryngeal ulcerations improved.[1]

I do not wish to compare these results with any other statistics, but offer them simply as contributions to the general stock of observation. The number of favorable cases of joint and bone tuberculosis strikes me as small, of pulmonary tuberculosis as large. When I ask myself what became of sixteen average cases of pulmonary tuberculosis admitted to our hospitals, before the inoculation epoch, the answer is very discouraging. It is true that most of the patients whose cases have been detailed above were placed in better conditions than ever before, and thus were given a more favorable chance for improvement. But so were all those who were admitted with tuberculosis any season, and any year; with hardly any resting place awaiting them but the dead-house.

Altogether, tuberculin has proven a remedy of great power for good, and for possible evil. It required credulous people believing in miracles to expect the impossible, and it took all the accumulated ignorance of centuries to believe in the possibility of reversing the rules of nature, which is as impartial in restoring as it is pitiless in destroying, subject to irrevocable laws. When great genii like Pasteur and Koch enrich the world with new discoveries in the fields of pathology and therapeutics, even then we must not look for infallibility. Tuberculin has been heralded as witchcraft by sensationalists. What it has done, and can do, is more than any other remedy —except climatic treatment in pulmonary tuberculosis, and surgical interference in select cases of local tuberculosis—has succeeded in accomplishing. From what little I have observed it would appear that the next future of successful treatment of pulmonary tuberculosis consists in the combination of climatic cures with the careful and persistent use of tuberculin. That is what we have to be thankful for even at this early date. At all events it is more becoming to honor our great men by appreciative criticism than to apotheose them first and exile them afterward. The former is the way of professional intellect and decorum, the latter that of a whimsical and flighty personal "government."[2]

REPORT OF A CASE OF GENERAL TUBERCULOSIS TREATED WITH KOCH'S LYMPH, WITH AUTOPSY.

By HENRY P. LOOMIS, M.D.,

NEW YORK.

MARTIN D ——, aged thirty-eight, married, wiremaker, was admitted into Bellevue Hospital on November 23, 1890, with rapidly advancing pulmonary tuberculosis. As he was steadily losing ground it was decided to try the effects of small injections of Koch's "lymph," especially as the patient and his family begged for the treatment. The patient gave no family history of tubercular disease. With the exception of one attack of acute rheumatism, and an occasional bronchitis, from which he always made a rapid and complete recovery, he had been strong and vigorous until six weeks before admission, when his present illness began, with a slight cough. His cough gradually grew worse, and was accompanied by loss of flesh and strength, and dyspnœa that became so urgent, and loss of strength so great, that he was obliged to give up work and come to the hospital. On December 23, 1890, he received his first injection of lymph, at which time a physical examination of his lungs showed diminished expansion and well-marked dulness at both apexes, most extensive on the left side. Large and small râles were heard in the intra-clavicular regions on both sides. Behind, in the left scapular region, there was tubular breathing, with large and fine crackling râles; in the right, fine crackling râles with crepitating friction-sounds. The patient weighed 142½ pounds. The amount of sputum per diem was one ounce, and from forty to forty-five tubercle bacilli were found to the field. The patient was daily injected with .00025 milligr. of the "original" fluid. After a week's treatment his condition was so much improved that he was able to be up and about the ward—his fever had decreased, and his night-sweats disappeared, and his dyspnœa was but slight. The patient remained in this condition for about ten days, the disease being apparently arrested, although no improvement in the physical signs could be detected.

On January 20th he began to expectorate blood, his temperature ranged from 102° to 104° F., his pulse became feeble and rapid. A microscopical examination of his sputum showed that the tubercle bacilli had increased from forty to fifty to the field. A loss of 6½ pounds since treatment began was noted, and a physical examination showed diffused infiltration of both lungs, with softening and excavation at the left apex.

The lymph injections were at once stopped, but the patient grew rapidly worse, and died on January 29th.

Autopsy, fourteen hours after death. *Brain:* There was intense congestion of the vessels of the cortex, with a moderate serous exudation into the meshes of the pia mater which showed in places an opacity. There were areas of intense hyperæmia in the brain, most marked at the cortex. A number of small, gray miliary tubercles were found along the fissure of Sylvius on both sides. Especially was this noticed on the left side where the pia mater was studded with small tubercular granulations for the space of an inch and a half. On no other portion of the brain were tubercles noted. *Heart:* Normal in appearance, weight 11 ounces, atheromatous patches occupied the first portion of the aorta. *Lungs:* The upper portion of the left lung was bound to the chest-wall by old adhesions. No adhesions were found on the right side. An old cavity, 5 ctm. in diameter, was situated at the apex of the left lung. It was surrounded by a fibrinous capsule one-eighth of an inch in thickness. The walls of the cavity were trabeculated, intensely congested, and covered with dark reddish-brown granulations. The cavity contained blood-stained necrotic-looking masses of cheesy tubercular material. There had been a hemorrhage into the cavity. Both lungs were studded throughout their entire extent with gray translucent tubercles the size of a pin's head; no normal pulmonary tissue could be found. Microscopical examination of the lung parenchyma showed the characteristic appearance of recent miliary tubercles, containing giant-cells in large numbers. Most of the alveoli between the tubercles were free of epithelial cells, but the capillaries in their walls were congested. In a few places cheesy pneumonic spots were noted. A section, including the wall of the cavity and the pulmonary tissue for three-fourths of an inch beyond, showed, under the microscope, 1st, a very intense hyperæmia of all the vessels, both in the old connective tissue which lined the cavity and in the walls of the adjoining cells. The hyperæmia was so great that in places hemorrhage had taken place; 2d, numerous areas of round-cell infiltration were noted; 3d, I saw nothing in or around the tubercles to indicate that a reparative process was being established. *Liver:* Weighed 4¾ pounds, was dense and of a dark mahogany color. A number of microscopical sections were made from different portions of the organ. Only a few contained miliary tubercles. The hepatic tissue showed a diffuse cirrhosis. *Spleen:* Normal size, soft, studded with miliary tubercles throughout its whole extent. The tubercles had the appearance of being of recent development. *Kidneys:* Weight of each 9 ounces. The left kidney was normal. Its supra-renal capsule, however, was intensely congested, and in places small

[1] A number of cases treated have not been accounted for, for the reason that the time of observation was too brief to yield any reliable result.

[2] To the house staffs of the German, Foundling, and Skin and Cancer Hospitals, I herewith express my appreciative thanks for their many and persistent labors connected with the accumulation of facts referring to the inoculations. They were indeed labors of love, with all of them.

hemorrhages had occurred in its substance. The right kidney was normal, with the exception in one place of a wedge-shaped eruption of miliary tubercles an inch across, involving both the cortex and medullary part. The collection of tubercles was easily recognizable to the naked eye, and on microscopical examination were seen by their structure to be of very recent origin. *Intestines:* The small intestines contained ten tubercular ulcers—some just forming, others of older date, but none showing the late changes of an ulcerative tubercular process. The largest ulcer was an inch and a half in diameter. The retro-peritoneal glands were enlarged, tubercular, and in places necrotic. *Stomach:* The mucous membrane of the stomach was intensely hyperæmic, and in places there were extensive submucous hemorrhages. No tubercles were found.

Remarks on the Case.—The interest in this case hinges on the questions, were tubercles present in the various organs before the injections were begun, or did they occur in the natural course of the disease, or were they produced by the lymph? The patient received in all twenty-four injections, as follows: fourteen of .00025 c.c. and ten of .0005 c.c.

Although the case was considered almost a hopeless one when the treatment was begun, at no time was it suspected that tubercular disease had extended beyond the lungs, for no symptoms of cerebral or intestinal tuberculosis were noted, even with a very careful daily examination of the patient by a number of observers. Most of the miliary tubercles found in the lungs were not of recent date. They had formed microscopical tubercular masses and contained necrotic centres. A microscopical examination of those found in the various organs showed a similarity in their stage of development. They were made up of giant-cells, well-marked epithelioid and lymphoid cells; they contained no cheesy centres, and, from their structure, must have been of very recent growth. The tubercular ulcers were confined to the small intestines and occupied the sites of the solitary and agminated glands. The appearance of the ulcers indicated that they were rapidly extending. The lymphatic glands showed an unusual degree of swelling, and a hyperæmia which extended to the innermost part of the gland, giving the appearance of glands which are the seat of an acute irritation. The physical signs of a cavity in this case were not distinct at the time of commencing the injections, but at the time of stopping the injections they had become very apparent.

Koch in his original article claims that the lymph produces necrosis around tubercular areas. Although a large number of sections taken from various portions of the lungs in this case were examined, in none of them did I find evidence of such a process.

The Absorption of Drugs in the Form of Ointments.—Dr. Luff says that certain drugs used in the form of ointments are most readily absorbed when the excipient is vaseline. Lanoline would be the best excipient when a local action of a drug is required, on account of its non-absorption. His experiments were made with iodide of potassium, carbolic acid, and resorcine, mixed with vaseline, lard, or lanoline. The mixture, contained in a sheep's bladder, was placed in a vessel of water, which was maintained at an equable temperature. The water was examined at short intervals in order to test the presence of the drugs. The exosmosis began in the case of the iodide of potassium with vaseline after one hour, with lard after nine hours; in the case of the carbolic acid with vaseline after two hours and a half, with lard after seven hours, in the case of the resorcine with vaseline after ten hours, with lard after fifteen hours. No exosmosis took place in the case of either of the reagents where lanoline was used within a period of twenty-four hours.—*Répertoire de Pharmacie.*

A SELF-RETAINING VAGINAL SPECULUM FOR OPERATIONS IN THE DORSAL POSITION.

By GEORGE M. EDEBOHLS, M.D.,
GYNECOLOGIST TO ST. FRANCIS' HOSPITAL, NEW YORK.

Up to three years ago, in common with the large majority of American gynecologists, I employed the Sims speculum and position for such operations as curettement of the uterus, trachelorrhaphy, amputation of the cervix, anterior colporrhaphy, for vesico-vaginal fistula, etc. At that time I began to operate with my patient in the dorsal position, with the thighs strongly flexed upon the abdomen, which I soon learned to prefer. During the past two years I have employed the Sims position only under the following single condition: After performing trachelorrhaphy or amputation of the cervix at the same sitting with hysterorrhaphy, or with shortening of the round ligaments, I have found the lateral position better adapted for the removal of sutures from the cervix. By its means the sutures can be reached without the necessity of dragging down the uterus and thus imperilling the result of the Alexander operation or of the ventro-fixation.

Soon after my conversion to the dorsal position I began to cast about for a self-retaining speculum for operative purposes in this position. I had realized from my previous experience as hospital interne the fatigue connected with holding a speculum for any length of time, and determined, if possible, to spare my assistants that infliction. Another more selfish motive was to get rid of the speculum-holding assistant's arm and hand, which are always more or less in the operator's way. The smaller number of assistants required presented still another advantage, especially valuable in private practice. A curettement of the uterus, for instance, provided anæsthesia can be dispensed with, can be performed without any expert assistance whatsoever, two relatives or friends of the patient to hold the legs constituting all the aid required.

FIG. 1.

I have discarded the use of sponges entirely in operations upon the cervix, vagina, and perineum, and employ in their stead continuous irrigation with sterilized water or an antiseptic solution. The dorsal position renders easy the employment of constant irrigation without wetting the patient's clothing, and is for this among other reasons to be preferred to the lateral.

Soon after I began to operate in the dorsal position I encountered in the *Annals of Gynecology* frequent allusions, by Cushing and Burt, to a modification of the so-called Martin speculum, made of lead pipe, self retaining by its shape, and acting as a perineal retractor by its weight. I made several of these for myself, but found them clumsy and unwieldy in use, and inapplicable, by reason of their weight and unsightly appearance, to the requirements of private practice.

The instrument depicted in Fig. 1 was made for me in the early part of 1888, and I have had it in constant use ever since. The speculum may be made of aluminium, or of copper or brass, nickel plated. The intra-vaginal blade forms, with the axis of the tubular handle, an angle of about forty-five degrees. This secures its self-retention when traction is made in a downward direction.

At its exit from the vulva the blade is provided with a broad flange on either side. These flanges take the place of lateral retractors in intra-vaginal operations.

That part of the speculum lying against the perineum is so curved as to adjust itself, *in the dorsal position with the thighs well flexed*, accurately to the perineum and anal region. It forms a shield to protect the operator against

surprises from the rectum of the patient. Should an alvine discharge occur during the operation it is guided by the front of the perineal part and of the handle of the speculum to the pail hanging beneath. Pollution and infection of the field of operation are thus prevented. The tubular handle conducts the irrigation fluids to the pail suspended beneath. This pail, of a capacity of about a quart, is filled with fluid, the weight of which furnishes the force retracting the perineum. The overflow from the pail runs into a larger basin standing beneath it on the floor. Any solid weight may, of course, take the place of the pail.

In the beginning of my experiments I had the instrument made in two sizes, or rather with two different lengths of the intravaginal blade. The longer blade I found especially serviceable in curettement of the uterus; as by its use the vagina could be kept filled with an antiseptic solution in which the external os could be held

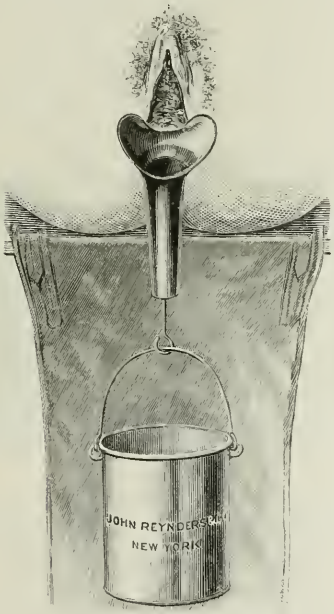

Fig. 2.

submerged during the performance of the operation. In those operations, however, requiring the uterus to be drawn down, the longer blade sometimes proved an obstacle by impinging against and holding up the posterior vaginal fornix. A shorter blade overcame the difficulty. Further experience, however, demonstrated that a blade of medium length answered all purposes.

The speculum is constructed and shaped for use in the dorsal position *with the thighs well flexed upon the abdomen*. An attempt to use it in any other position, as for instance the dorsal with the thighs perpendicular to the surface of the table, will inevitably result in disappointment. This source of failure has obtained, to my knowledge, in the practice of several physicians. As an instance of how constituted some men are to appreciate the eternal fitness of things, I may cite the case of a confrère whom I met in one of the shops inspecting the instrument. He regarded the blade as the handle, and was profoundly absorbed in a study of the value of the tubular handle as a cylindrical speculum, for a variety of which he evidently mistook the instrument.

The patient's hips should, of course, be drawn down to or even a little beyond, the very end of the table, so as to allow free swinging room for speculum and pail. The index finger of the left hand is introduced well into the vagina, pulling down its posterior wall and depressing the perineum. The blade of the instrument is next slipped in and, on adjusting the pail filled with water in the manner depicted in the cut and withdrawing the index finger, the speculum adjusts itself in position, *provided always the thighs are well flexed upon the abdomen*. The cervix is now seized with a double tenaculum forceps and, in the absence of peri-uterine adhesions and exudates, can be readily brought down to the vulva.

An instrument very similar to my own is depicted in the *Annual of the Universal Medical Sciences*, issue of 1889, vol. ii., E-65. It is designated Jones-Martin speculum, and the cut is credited to the *Medical and Surgical Reporter*. On careful search through the files of the latter journal I was unable to find a description or cut of the instrument.

Another instrument, based upon the same idea, is figured and described in the *American Journal of Obstetrics*, 1887, No. 5, p. 549. It was presented by its originator, Dr. George D. Jones, at a meeting of the Obstetrical Society of Cincinnati on January 13, 1887. In answer to my inquiries Dr. Jones informs me that he improved his instrument soon after its first presentation. I quote from Dr. Jones's letter: "With my instrument the angle of the blade is gauged by the angle of the handle, and a rubber hose attached by a small thimble so that the fluids pass off into a bucket or basin. The so-called Jones-Martin speculum (above alluded to) I have nothing to do with."

In the *Nouvelles Archives d'Obstetr. et de Gyn.*, 1889, No. 5, Nitot describes a self-retaining speculum with tubular handle. It consists of a retractor for the anterior and another for the posterior vaginal wall. The anterior blade is operated by pulleys and weights acting from a gallows-like structure swinging above the patient. The posterior blade is retracted by a mechanism attached to the legs of the table. The entire apparatus appears much too complicated and non-practical to be adapted to general use.

As will be seen from the above, practically the same idea has occurred to several men, and each has elaborated it in his own way. I demonstrated my instrument at a meeting of the Gynecological Section of the Tenth International Medical Congress recently held at Berlin. Our German confrères, who operate all but exclusively in the dorsal position, were pleased to accord it a favorable reception.

A British View on Cremation.—Cremation commends itself as an excellent way of ending an essentially unpleasant business. The best of us succeed in making ourselves disagreeable to someone or the other during our lifetime, and we are all unintentionally offensive to everybody else when we have ended it. Then, in Heaven's name, have done with it as soon as possible! And the picturesque funeral pile, or the modern matter of-fact furnace, makes the speediest end our ingenuity has yet devised. To men of classical tastes the recollection that the pyre was the chief and most honorable mode of sepulture during those glorious days when the human intellect seemingly towered to its topmost height, when the brain of gods and not base mechanic hands ruled the world, may add another and not the less potent because a sentimental plea. And to us the thought that Hippocrates and Galen, in those far-off days when medicine was "the noblest of professions," and not, what the teaching of the *British Medical Journal* and the blare of Birmingham trumpets is fast making it—the worst-paying of trades—so yielded up all that could decay and pass away, and, also, that the most effectual way of disposing of disease-germs is to burn them, should alike weigh down the doubtful balance beam.—*The Provincial Medical Journal.*

A CASE OF TUMOR OF THE LARYNX, SHOWING AMYLOID DEGENERATION.

By FRANKLIN H. HOOPER, M.D.,

BOSTON, MASS.

The chief interest of this case arose from the unusual histological structure of the tumor. But besides this, it was interesting to me as being the largest pediculated intra-laryngeal growth met with in my practice, and from the fact that tumors of the larynx are rare in this country compared with the published statistics of their frequency in Europe; for, out of the last 7,500 patients who have come under my observation, either at my hospital throat clinics, or in my private practice, non-malignant tumors of the larynx have existed in but twenty-one cases.

The patient, a very stout, thick-set man, aged fifty-three, consulted me December 20, 1889. His sole complaint was hoarseness. This began, he thought, with an ordinary cold four years previously. The hoarseness had steadily increased, and during the two months immediately preceding consultation, articulation had become almost impossible. Examination with the laryngoscope revealed the appearances shown in Fig. 1. The growth moved slightly with forced respiration. It appeared to be attached to the superior surface of the anterior region of the left vocal cord, but after its removal it was determined that it originated also from a portion of the ventricle. The surface of the tumor was smooth, and presented a mottled appearance, being of a deep-red color with spots of a paler hue dotted over its surface.

Fig. 1.—Actual size.

The case was an unpromising one for an intra-laryngeal operation, owing to the excessive irritability of the patient's throat. His *bonne volonté*, however, compensated for the difficulties involved in operating, and after a few unsuccessful attempts, accompanied by the patient's vomiting in one of them, a loop was passed under and around the growth, and the tumor was removed *en bloc*.

Previous to this the larynx and pharynx had been showered liberally with a four per cent. solution of cocaine. This may seem a weak solution to use for the purpose, but in my experience, when cocaine acts at all in these irritable cases, a four per cent. solution is as efficacious as one of twenty per cent.

The size and shape of this growth, and the limited surface of its attachment, made it evident that the snare was the proper means to employ for its removal. The instrument by which this was effected is shown in Fig. 2.

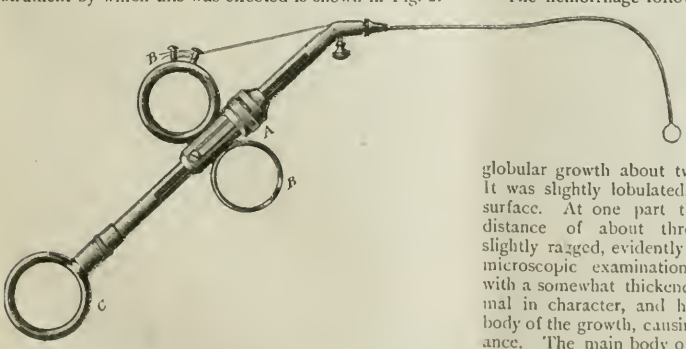

Fig. 2.

The handle of this instrument is the same as that described by me in the Boston *Medical and Surgical Journal*, December 19, 1889, under the name of "A Combined Nasal Snare and Écraseur." For laryngeal operations a cannula having the Schrötter curve may be adjusted to the handle. The merit of this instrument is that it can instantly be changed from a snare into a powerful écraseur. For when the collar *A* is to the left the rings *B B* may be freely moved up or drawn down as in ordinary snares. On turning the collar *A* to the right the screw-thread of the instrument becomes engaged, and the result is a perfect écraseur, the rings *B B* with the wire attached moving downward only as the screw is operated by turning the ring *C*. With this instrument, therefore, one need

feel no apprehension of getting the loop around a tough growth and being unable to pull the growth off or to extricate the snare. Although the tumor in this instance came away without much force on my part, I should have hesitated about using any other form of snare for its removal.

The hemorrhage following the removal of the growth was considerable for an intra-laryngeal operation, but it ceased completely in a few minutes. Dr. William F. Whitney's report of his examination of the tumor is as follows:

"The tumor, which had been preserved in alcohol, was a globular growth about twelve millimetres in diameter. It was slightly lobulated, and in general with a smooth surface. At one part the surface was broken for the distance of about three or four millimetres, and slightly ragged, evidently the point of attachment. On microscopic examination the surface was seen covered with a somewhat thickened layer of epithelial cells, normal in character, and here and there sinking into the body of the growth, causing the slightly lobulated appearance. The main body of the growth was made up of a tissue which in places was composed of elongated, spindle- and star-shaped anastomosing cells, leaving spaces which were filled with a fluid containing a substance coagulable by alcohol (mucin). In other parts the tissue was more fibrous, and many of these fibres were thickened and hyaline. In a few places were irregular

rounded masses of transparent material, with a few small scattered nuclei, and which stained a mahogany-brown in liq. iodinii comp.

"The tissues were traversed in all directions by large blood-vessels, and here and there were clumps of blood-pigment (pointing to previous hemorrhages). The coats of the blood-vessels, in places, were transparent and took the same mahogany-brown color as above.

"The diagnosis is a telangiectatic myxo-fibroma, with hyaline and amyloid degeneration. The accompanying drawing (Fig. 3) shows the principal points of the structure of the growth above described." The patient, living a long distance from Boston, has not been seen since the operation. He writes me, however, under date of October 17, 1890, that his voice, which was fully restored by the operation, continues in its normal condition; so it may be presumed that there has been no recurrence of the tumor.

Progress of Medical Science.

Scrofulous Kidney.—At a recent meeting of the Manchester Pathological Society, Dr. Railton showed specimens from a case of scrofulous kidney in a boy, aged two years and nine months, who had been an in-patient at the Manchester Clinical Hospital. A tumor was observed on the left side of the abdomen, extending from the ribs to the iliac crest, and reaching as far forward as one finger's breadth in front of the vertical line of the anterior-superior iliac spine. There was no movement of the tumor during respiration, and the percussion note over it was dull. There was, in addition, some slight dulness over the apices of both lungs. One month after admission the child died of tuberculous meningitis. After death, the left kidney was found to be four or five times its normal size, and almost completely transformed into a caseous mass; its pelvis and calyces were dilated, and contained purulent fluid. The ureter was completely closed, accounting for the fact that the urine showed nothing abnormal. The apices of both lungs showed infiltration, caseation, calcification, while that of the right showed, in addition, a small cavity. The brain showed a considerable quantity of fluid in the ventricles, exuded lymph in the space between the optic chiasma and pons and along the sylvian fissures, tubercles on the lower surface of the lateral lobes of the cerebellum and in the longitudinal fissure. Dr. Railton remarked that the disease in the left kidney had probably existed for a long time before that in the lungs, and had no causal relation to it, and that the meningeal tuberculosis was of quite recent date. He asked whether some distinction should not be drawn between a slow caseating process like that in the kidney of this case, or as frequently witnessed in tumors of the cerebellum, and the rapidly disseminating process known as acute tuberculosis.

Dr. Dreschfeld would have expected to find, from Dr. Railton's description of the *ante-mortem* appearances, the kidney much larger than it turned out to be, but had often noticed similar discrepancies in other abdominal tumors. He did not consider that any real difference existed between this class of case and ordinary tuberculosis. The presence of baciili in the urine would be conclusive evidence in a similar case, but in this the blocking of the ureter rendered such appearance impossible.

Treatment of Habitnal Abortion.—At a recent meeting of the West London Medico-chirurgical Society, Dr. Napier read a communication on this subject. He classified the various methods of treatment under four headings: 1, Rest or exercise, insisting on the necessity of absolute rest for at least six days in the month; 2, local cure of uterine disease, chronic endometritis being regarded as the chief cause of abortion, in that retroflexion and other displacements, with atony of the mucous membrane, leucorrhœa, etc., were regarded as resulting from chronic uterine inflammations or congestions; 3, constitutional treatment; and 4, drug treatment. The value of local treatment was strongly urged, and in estimating the comparative utility of drugs the prolonged exhibition of mercury, even in cases of a non-specific nature, was extolled above all other therapy, while as a uterine sedative viburnum was preferred to any other drug by the author of the paper, in whose practice seventy-seven per cent. of habitual aborters had borne living children after treatment by local methods and drugs.

Milk Diet in Scurvy.—Dr. Tchelzoff recommends an absolute milk diet in scurvy. This year during the epidemic of scurvy in Russia 148 patients were admitted to the hospitals, of which 30 were subjected to absolute milk diet. The 30 cases treated by the author were extremely severe ones, presenting œdema of the legs, and especially of those limbs that were more subjected to exercise. For the sake of experiment, some of the selected cases were put in the beginning on a mixed anti scorbutic and milk diet, from four to five glassfuls of milk being given daily. The improvement in these cases was very slow. An absolute milk diet was then substituted, beginning with from four to five glassfuls of milk, and increasing the quantity of milk from one-half to one glassful a day, no medicine being administered. The author's conclusions are: 1. An absolute milk diet aborts the scorbutic process in any period of its course. 2. With the above method of treatment there is no recurrence. 3. With the above method convalescence is established much quicker than with the ordinary anti scorbutic treatment. Thus, out of twenty-eight cases, nineteen recovered in eight days. On an average five cases recovered in two weeks, and four cases recovered in three weeks. 4. The addition to the milk of the smallest amount of any other article of diet protracts the recovery.—*Medical ana Surgical Reporter.*

Experimental Peritonitis.—Dr. Waterhouse, in a series of twelve observations, confirmed the results of Grawitz, and negatived those of Pawlow-ky, that a considerable quantity of a virulent culture of the staphylococcus aureus might be injected into the abdominal cavity without causing peritonitis. Also, when the staphylococcus is mixed with an untried medium it causes no disturbance if the mass can be readily absorbed; the greater the difficulty of absorption the more certain the production of peritonitis. Trials were made with agar-agar, gelatine, and coagulated blood, each containing the staphylococcus, and the results were positive. Pus containing the staphylococcus possessed strong pyogenic properties, due, the writer thinks, more to its contained chemical substances than to its micro-organisms. The observation of Grawitz, that when the infection was introduced through a wound in the abdominal wall peritonitis followed, was not confirmed. When the wound was pencilled with turpentine an abscess was produced, but only in cases where the wound involved the peritoneum; if it extended only to that membrane and not through it, no abscess was caused. When artificial defects were produced in the peritoneum injections of the staphylococcus caused peritonitis; a similar effect was produced in animals affected with ascites. A strangulation of the intestine for some hours, similar to that produced by a hernia, invariably caused peritonitis after the injection of the staphylococcus into the abdomen or blood-vessels. The same result was reached if the coccus was injected subcutaneously, but not if it was placed in the intestine. A few observations upon man has shown that the staphylococcus may be injected under the healthy skin without danger, but that suppuration follows if the absorption is hindered or the normal conditions are altered by passive hyperæmia.—*Journal of the American Medical Association.*

Chlorosis and its Treatment.—Dr. Scholz, of Bremen, has published a remarkable work on chlorosis, the outcome of observations made during the last twenty years. In

stead of regarding the deficiency of iron or hæmoglobin, or even that of the red corpuscles, as the primary affection, he states that contraction of the vessels is always present in these cases, as, indeed was observed by Bamberger, Rokitansky. and Virchow; and this, he contends, is not to be regarded as a complication due to an altered condition of the blood, but as the primary condition which is followed by the morbid change in the blood. As a matter of fact, the vessels are, he says, too full, or in the condition termed by the older physicians "plethora ad vasa," the blood being—or becoming—abnormally serous. Long ago his attention was struck by the cold and livid condition of the skin in anæmic subjects, and he was led by this to employ hot baths, together with gentle friction, in the treatment, with a view of acting directly upon the skin, so as to improve the vitality and nutrition generally. The success of his first attempts was so marked that he was encouraged to persevere in this line of treatment, and he has since had many opportunities of extending his experience with it. Hot baths diminish the plethora by relaxing the tension of the vascular system, which is high, quickening the circulation, and thus relieving the palpitation, dyspnœa, and other symptoms. In thirty cases where the distress of the patient was very great, Dr. Scholz has gone a step further and supplemented the hot bath by venesection. Paradoxical as this treatment may appear, it was followed by marked benefit, and if the theory of the pathology of chlorosis above mentioned be correct, there can be little doubt that the novel line of treatment practised by Dr. Scholz is justifiable.—*The Lancet.*

Retinol in Medicine.—This drug, C_{56}, H_{10}, and at present but little known, seems destined to play an important part in medicine as a vehicle and dissolvent of substances but slightly soluble. Discovered in 1858 by Pelletier and Walter, retinol, under its erroneous designation of resinol, remained in obscurity till 1890 when it was employed successfully by Dr. Balzer in specific vaginitis, syphilitic and varicose ulcers. In the issue of *Médicine moderne*, February 14, 1891, there is a description of the drug, together with its present pharmaceutical and therapeutic range. It will dissolve many antiseptic agents, and is without irritating effect. Salol is soluble in ten parts of retinol, iodol, naphthol, and aristol in fifty parts, camphor in twenty, chrysophanic acid in forty, cocaine in thirty, and strychnine in forty parts of retinol. Camphorated naphthol is very soluble in this substance. Oil of Cade mixes with it in any proportion, and also phenic acid, essence of terebinthine, alcohol and ether. Resorcin is dissolved first in a small quantity of glycerine before the retinol is added, and iodoform must first be treated similarly with ether. Iodine is also soluble in retinol, but a resinous substance is shortly deposited. Retinol combines readily with fatty matter, with oil, vaseline, ointments, lanoline, oleonaphthine, and glycerine, even replacing the latter at times with advantage as an antiseptic, except where greater consistency or the presence of glycerine is required. In specific vaginitis tampons saturated with pure retinol are used, or suppositories of equal parts of white wax or soap and retinol. Tannin, borax, and colophonia may be added. In gonorrhœa in the male retinol may be employed alone as an injection, or associated with resorcin in parts of three to one hundred; and administered pure in capsules, or mixed with salol. In skin diseases, as psoriasis, it is combined with starch, naphthol, and oil of Cade.

Politzerization.—Dr. H. MacNaughton Jones gives the following hints as to Politzer's method of treatment. 1. Let the patient be seated—at times patients become slightly giddy on inflation of the tympanum. 2. Make the patient swallow some sips of water in rapid succession, or pronounce, through the nose, the vowel "o" a few times—this assists in opening the Eustachian tube, and is a form of "gymnastics" of the palatal muscles. 3. Incline the head to either side—inflate through the nostrils opposite to the side to which the head is inclined. 4. Direct the current horizontally. 5. Experimentally ascertain whether any form of nasal phonation or the act of deglutition best dilates the aperture of the Eustachian tube. Adopt this method with the individual case. 6. After politzerization make the patient again swallow several sips of water. 7. With children, phonation is the best act to take advantage of; we can, as a rule, inflate when the child cries; with the auto-inflating bag there is seldom any difficulty—children quickly learn to inflate the middle-ear. Finally, let me enumerate the conditions in which the method of Politzer will be found of the greatest assistance in treatment. 1. In temporary collapse or closure of the Eustachian tube from catarrh of the naso-pharynx. 2. In collapse of the Eustachian tube from enervated states of the tubal muscles. 3. In chronic catarrhal conditions of the naso-pharynx and attendant chronic catarrhal conditions of the tympanum. 4. After intra-tympanic alkaline injections or douchings of the Eustachian tube. 5. After the use of the Eustachian catheter or bougie. 6. In chronic perforation of the membrana tympani, after cleansing of the middle ear, and before applying an artificial membrane. 7. After removal of impacted cerumen. 8. For cases of tinnitus dependent upon abnormal states of the middle ear. 9. For similar cases attended by vertigo. 10. For temporary deafness which attends on seabathing or diving. 11. In cases of deafness dependent upon obstructed nasal respiration. 12. In collapse of the membrana tympani. 13. In those cases of "progressive deafness" in which there is some degree of fixation or rigidity of the ossicles.—*Medical Press.*

Péan's Treatment of Stricture of the Ileo-cæcal Valve.—According to Dr. Péan, stricture of the ileo-cæcal valve is very rare. Up to the present only eight cases are on record. They might be divided into two classes—those of a neoplastic origin, and those derived from inflammatory causes. Surgeons treated these cases in different ways. Maydl, Barton, and Jessop made an artificial anus above the stricture, while Krausold did not hesitate to resect the parts. Péan devised an operation consisting of dilatation of the narrowed part. An incision parallel to Poupart's ligament and about an inch and a half above it, is made from the superior and anterior iliac spine to the spine of the pubis, dividing the skin and the cellular tissue. A shorter incision is made through the aponeurosis and the muscles, the peritoneum is opened for about an inch and three-quarters, and the cæcum is reached. Hæmostatic forceps are placed on every bleeding vessel, and antiseptic plugs surround the orifice, in order to hinder any suspicious fluid from entering the cavity. As soon as the ileo-cæcal valve is brought to view, the neighboring portions of the cæcum and the ilium are drawn on and tied above and below the valve with two tubes of india-rubber, the loops of which are passed through the mesenteric portions of the intestines by a sharp forceps, and the extremities of the tubes are maintained by a kind of blunt artery-forceps. These tubes not only prevent hemorrhage, but hinder the circulation of fecal matters during the operation. After these precautions the wall of the intestine over the valve was incised for the space of three inches and the interior washed with an antiseptic solution, and the valve examined. It is generally found to be transformed into fibrous tissue and studded with fleshy growths which narrow considerably the orifice. These growths are cut away, and the primitive wound closed by sutures, turning the lips inside so that the occlusion is perfect. The sutures are double, deep, and superficial. This operation terminated, the loops of india-rubber are withdrawn, and immediately the blood is seen to circulate in the vessels, and the fecal matter to move forward with astonishing rapidity. Iodoform dressing is applied, and the patient carried back to bed. Two patients operated on by this method did remarkably well.

Scrofuloderma.– Unna divides scrofuloderma into two classes: 1, That resulting secondarily from tuberculosis of other organs, as bones and joints, generally with the formation of white swellings resulting in fistulous tracts; and 2, primary scrofuloderma. This may again be divided into two sub-classes, according as the cases begin as well-defined lupus, on points of which may appear doughy, pale-red swellings with a marked tendency to suppuration, or on the other hand, the lesions appear independently of any previous lupus. In these last cases there appears a small subcutaneous nodule, which grows toward the cutis and then slowly, though spontaneously, develops into an abscess. This spontaneous suppuration in scrofulodermata suggested to Unna the possibility of there being here more than a simple tuberculous infection, that is to say, a mixed tubercle and pus-coccus infection. According as one or the other disease-producer occurred in excess in the tissues, so would the tubercular or purulent nature of the affection be the more prominent. Should the pus-cocci form the second invasion on a soil already tuberculous, they find a tissue below par vitally, one in which they could not give rise to a frankly phlegmonous inflammation, and in consequence there would result a gummy softening of the tissues, a "moist caseation" or "gummy tuberculization." Dr. Leistikow applied to this theory microscopical and bacteriological tests in Unna's laboratory. He employed excised portions of scrofulodermus from which he obtained cultures of staphylococcus aureus, even from the deepest parts of nodules which had been covered with unbroken skin. He was unable to obtain cultures of B. tuberculosis. A single specimen of the latter was, however, found in sections. Numerous tubercles were to be seen, and round-cell infiltration, especially in the papillary layer. The results of these researches seem, therefore, to establish Unna's theory.—*Weekly Medical Review.*

The Gastric Functions in Cancer of the Stomach.—Dr. Voinovitch, of St. Petersburg, has published a monograph on this subject, based on his elaborate observations on twenty-one cases of gastric cancer. Of the number sixteen cases referred to men aged from thirty-four to sixty-three, and five to women aged from forty to sixty. Twelve patients were suffering from malignant disease of the pylorus, with a more or less marked stenosis of the orifice; three from a diffuse new-growth, involving mainly the posterior wall of the organ; four from cancer of the cardia and œsophagus; and two from that of the gastric end of the gullet. In nineteen out of the twenty-one cases the diagnosis was subsequently confirmed by the post-mortem examination. A general or total acidity of the gastric juice was appreciated by means of a decinormal solution of caustic soda, an alcoholic solution of phenol-phtaleïne being used as an indicator. The presence and proportion of hydrochloric acid were determined after Sjöquist's method, as well as by means of various color-tests, such as tropæoline-oo, methyl-violet, congo-red paper, phloro-glucine-vanilline, Lépine's *vert brillant*, etc. The motor power of the stomach was examined after Ewald Sievers's method (consisting in the internal administration of salol, with a subsequent treatment of the urine by perchloride of iron), and the absorptive power after Penzold-Faber's plan (by the internal use of iodide of potassium, with a subsequent examination of the saliva for iodine). The principal corollaries deduced by Dr. Voinovitch from his investigations may be summed up as follows: 1. In cases of cancer of the stomach the gastric juice undergoes profound alterations. 2. In a vast majority of the cases (in nineteen out of twenty one) no free hydrochloric acid can be detected in the juice. (The statement is based on two hundred and eighty-seven analyses.) 3. Pepsine seems to be also absent—at least, in a considerable majority of cases. 4. Hammarsten's ferment (*Labferment*) is invariably absent. 5. In cases of pyloric malignant disease the motor power of the stomach is greatly lessened; in those of cancer of the cardia and œsophagus it remains normal, or sometimes even increases. 6. The absorptive power of the organ is always diminished, and that usually to a considerable degree. 7. As a diagnostic sign (in cases of gastric cancer), the absence of hydrochloric acid from the juice is not less characteristic and reliable than the presence of a tumor in the gastric region.—*The Provincial Medical Journal.*

Operations for Uterine Fibroids. — Dr. Martin, of Berlin, announces the following views: 1. Enucleation per vaginam should be limited to cases in which the tumor is of small size and in which there is already a tendency to extrusion. 2. If the uterus is the seat of fibroids, but is still movable in the pelvis, the tumor being small relative to the calibre of the vagina, extirpation of the uterus per vaginam is to be recommended in case the condition is one which calls for operative treatment. 3. Large tumors which must be attacked by the abdominal cavity should be excised without the removal of other structures if possible. Whenever it is possible, the ovaries and tubes should be allowed to remain, together with a sufficiently intact uterus for the performance of its customary functions. 4. Enucleation of myomata during gestation, by abdominal section, may be regarded as a perfectly proper operation in the light of present experience. 5. If the uterus cannot be retained it should be removed entire with the tumor, the question as to the intraperitoneal or extraperitoneal treatment of the pedicle being a matter upon which no positive directions can be given at present. —*Zeitschrift für Geburtshülfe und Gynækologie.*

Cysts of the Epididymis.—Dr. Poirier discusses the three prevailing theories as to the formation of cysts of the epididymis, namely, from the remains of the Wolffian body; from rupture of spermatic tubules; and, lastly, from retention cysts. These three theories correspond to the three varieties of cysts which actually exist, but the last seems applicable to the greatest number. Professor Roth's observation, that vasa aberrantia often spring from the rete testis, is confirmed. Forty-three testicles were injected with mercury, and in twenty-five a vas aberrans sprang from the rete testis, usually at the junction of the head of the epididymis with the body of the testicle and at the top of the digital fossa. This unrecognized blind tube probably orignated from one of the tubules of the Wolffian body, and by accumulation of fluid within it gave rise to cysts; these, as they grow, acquire communication with the spermatic ducts, and become spermatic cysts. Serous cysts are next described, and are said to originate in three situations: between the head of the epididymis and testis, at the middle part of the body of the epididymis, and between the tail of the epididymis and testis. They were not to be confounded with the serous cysts found in old men, nor with those due to faults in the seminal tubes, and which are lined with columnar ciliated epithelium. On the contrary, this variety was lined with two kinds of epithelium, namely, ciliated and pavement. Also, they are capable of growing to a considerable size and of becoming true spermatic cysts. Like cysts in other regions, they owe their origin to traumatism or to inflammation, and only acquire their communications with seminal tubes at later stages of their existence, after which they grow rapidly. Further, the adhesions which the epididymis and testes form with one another after birth are a factor in the formation of these serous cysts. The conclusion arrived at by Dr. Poirier is that the retention theory does not account for the formation of a great many cysts of the epididymis, and that there is a variety of serous cysts which originate during the adhesion of the epididymis to the testis, and which afterward form communications with spermatic ducts, and then rapidly increase.—*Revue de Chirurgie.*

Causes of Drug Eruptions.—Dr. Brooke comes to the conclusion that all the many-sided phenomena of the drug exanthemata are, as far as the vascular system is

concerned, reduced down to one single element, that of vascular paralysis or hyperæmia. When a simple paralysis occurs we have a simple erythema, which can, when the epidermis has little power of resistance, give rise to vesiculating and bullous erythemata; or again, when a spastic element concurs, the erythematous basis may develop into papules like those of erythema multiforme and nodosum, or into wheals; or, finally, where a passive condition takes the place of the active hyperæmia, conditions of purpura and œdema may be produced. All these different types depend not on the constitution of the vascular and nervous systems, but in the peculiarities of the skin itself, and vary according to its individuality. Thus we see that the limitation of these seven main types and their connecting links are after all not so very remarkable as one is led to believe. We can, as we follow the drugs first in their influence on the nervous system and then on the skin itself, explain the different peculiarities which distinguished the purely angeio-neurotic drug exanthemata. But there are some which in addition present more pronounced symptoms of inflammation, as the persistent scarlet rash due to quinine, followed by desquamation. Here we have to recognize, in addition to the angeio neurotic influence of the nerve-centres, a local direct influence of the drug circulating in the blood on the tissues of the skin itself.—*British Journal of Dermatology.*

Diabetes Mellitus in Children.—Dr. W. Kühl discusses the points of difference between diabetes in the adult and in children. In point of sex, in the first place, there is a marked difference, diabetes being more frequent in males in the adult form and in females in children. In regard to etiology heredity plays an important part, as diabetes or some form of nervous disease had always shown itself among the ancestors. There is also a possibility of injury being a cause among children. The symptoms as a whole are the same, but one may be almost looked upon as specific as regards children, and that is the high percentage of sugar. The course is generally much more rapid in children, as might be expected, diabetes being a disease of abnormal tissue change, and this is more likely to prove injurious in persons in whom tissue growth is proceeding. In cases of true diabetes mellitus in children the prognosis is absolutely unfavorable. As regards the various forms, opinion is still divided. One is that the so-called mild form is only an early stage and that it passes by transition into the graver one. Others, again, believe this is never the case. The author gives his adherence to the former belief. The transition from the milder to the graver form takes place the more rapidly the younger the subject. The graver cases are met with more frequently among the poorer classes, the cause being that among them the milder cases pass undetected, and the disease passes unnoticed from one to the other. This also takes place among the better classes if the mild form continues long unrecognized.—*Medical Press.*

Why the Stomach does not Digest Itself.—From a new study of this subject Dr. E. Sehrwald announces the following conclusions: 1. The balance between the alkali of the blood and the acid of the gastric juice does not follow, during life, the law of diffusion, but moves in narrower limits. 2. The self-digestion of the stomach is partly prevented by the alkalinity of the blood and partly by cell-action. 3. The living epithelium interposed between the blood and the gastric juice prevents their mutual neutralization and preserves the alkalinity of the blood and the acidity of the gastric juice. 4. By this protection the stomach is spared a great deal of work of secretion and absorption. 5. The protection furnished by the flowing blood is partly due to its alkalinity and partly to its properties as a nutritive liquid. 6. All influences which arrest the nutrition of the cells of the walls of the stomach, may lead to self-digestion and ulceration. The conditions which may be mentioned in this connection are, first, disturbances in the circulation, second, direct injury to the epithelium, and third, injuries of the trophic nerves.—*Münchener Medizinische Wochenschrift.*

Calcareous Degeneration of the Pleura. Dr. Poulaillon read a paper on this subject before the Anatomical Society of Paris. Three cases were described. The first was of traumatic origin. A blow on the right side of the thorax, followed by hæmato-thorax, occurred fifteen years before the death of the patient from phthisis. The calcification was advanced in the right pleura. The second patient died from cancer of the right kidney, with severe hæmaturia. Nothing abnormal could be detected during the patient's last illness, in the thoracic viscera, nor was there any evidence of a previous attack of pulmonary disease. Nevertheless, the lateral and posterior aspects of the two lower thirds of the right lung were covered by a fibro-cartilaginous and fibro calcareous shell consisting of pleura. The third case is of special interest to surgeons. A man, aged fifty, entered a hospital for the cure of a pleuro-thoracic fistula in the seventh intercostal space on the left side. It was the result of tapping for empyema five years previously. The sound introduced into the fistula touched the extensive rough surface of some hard substance. Caries of the rib, with the formation of costo-pleural osteophytes, was diagnosed, and there appeared to be sequestra, which moved freely when touched by the sound. The fistula was dilated with a laminaria tent, to aid exploration. By this procedure, a splinter-like fragment of a bony substance, resembling a sequestrum, came away. So evident, at the time, seemed the nature of the disease, that the fragment was not examined by a pathologist. The operation for resection of the rib was commenced; but on reaching the rib that bone was found perfectly healthy. Extensive calcification of the pleura was detected; the finger could be passed into a narrow but extensive space between the calcified visceral and parietal layers of the diseased serous membrane. A gritty semifluid material filled this space. A large calcareous fragment was pulled out, the pleura was washed out with an antiseptic solution, and the wound dressed antiseptically. The fistula did not entirely close, but the patient left the hospital with his health much improved. Pathological research shows that these plates are first developed through hyperplasia of the subendothelial connective tissue of the parietal layer of the pleura; they are seldom, if ever, of purely pulmonary origin. Traumatism is the most frequent cause of their development. Diagnosis by physical signs is seldom possible.—*The British Medical Journal.*

The Three Kinds of Diabetes.—According to Professor Lancereaux there are three kinds of diabetes. 1. Traumatic diabetes, which appears after injuries to the brain and spinal cord. There is moderate polyphagia, polydipsia, polyuria, and glycosuria, and the prognosis is generally favorable. 2. Pancreatic diabetes. This is the form ordinarily called diabetes mellitus. It is characterized by severe polyphagia, polyuria, and glycosuria. It is supposed to be due to some disease of the pancreas. 3. Adipose diabetes. The symptoms are of moderate severity and the excretion of sugar scanty.—*L'Union Médicale.*

Antipyrin in Chorea.—The *Journal de Médecine et de Chirurgie*, February 10, 1891, states that Dr. Charles Leroux finds antipyrin of great value in chorea, good results having been obtained through its use in two thirds of the cases, in forty one out of sixty. It quickly diminishes the intensity of the disease and shortens its duration. Large doses are necessary, as much as three, four, or six grammes from the start, according to age. Children from six to fifteen years of age can tolerate and take with advantage doses ranging from three to six grammes for several weeks in succession.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, March 7, 1891.

DISEASES NAMED FOR DOCTORS.

THE number of diseases with proper names is constantly on the increase, to the detriment of language and to the confusion of the general practitioner. Every one who describes or discovers some pathological entity of moment straightway foists his name, or others foist it, upon the unoffending peculiarity, and the result is an amount of lumber in regard to medical nomenclature that is fast becoming a definite obstacle to clear thinking and exact reasoning. There are now over one hundred and ten diseases, or symptoms, with proper names as marks of distinction. The busy scientific student may well be forgiven if, under the circumstances, Ritter's disease, the malady of Concato, together with that of Tomaselli, Donders, Corrigan, and Fouchard are all *x*, and represent to him an unknown quantity. It is possible to be brave, dutiful, and dominant, as Carlyle describes the apeptic man, and yet remain ignorant of Kennedy's paralysis, Riehl's tuberculosis, Worms's symptom, and Blainville's ear. Any one whose soul is not steeped in neuro-pathology will be pardoned here and hereafter for confounding the muscular atrophies that are forced by a perverse generation to parade as the type Duchenne (of Boulogne), Charcot-Maire's type, Erb's type, the Lyden-Möbiers, the Zimmerlin, and the Landouzy-Déjerine type. Clearness and terseness of description is also to be desired in the literary treatment of disease. Renant has recently described chronic essential segmentary myocarditis, and not content with three adjectives as qualifiers has bestowed upon the unfortunate noun his own name. Prolix and exhausting as exercises of memory are the cardinal symptoms of this new disease, to wit, true arhythmic multiform pulse, effacement of localized precordial impulse, together with rectangular dulness of the heart, and a medio-cardiac murmur. Pity the sorrows of a poor young student, at a final examination, before some obdurate professor who requires a description of Renant's disease (of Lyons), and refuses to be pacified by a carefully worded account of Raynaud's disease! Such modern tricks of naming things recall Talleyrand's witty remark that language is given us to conceal our thoughts. The thoughts of Raynaud and Renant suffer definite loss because their names qualify, in the grammatical sense, disorders of widely different nature. There is another side of the question, too, that is well worth considering. Who wants to stand sponsor for a disease? Who cares to have his name associated forever with some special form of pain and suffering, with limitations and inconvenience, with wakeful nights and unhappy days? An act, a method, an invention, or artifice for the relief and cure of abnormities, may well bear its author's name, and thus become a lasting encouragement to those performing in patient obscurity offices of drudgery along similar lines. However trivial the deed or contrivance, anything that makes the world brighter and better deserves honorable mention. But the sensitive must naturally shrink from giving a good name—perhaps a proud inheritance—to pathological processes that are necessarily vicious and destructive.

Taking language at its word, according to its spirit and the laws that govern it, the absurdity of the present practice becomes at once apparent. Judging by the simple meaning of the terms used Hutchinson has teeth and a triad, Morand has a foot, and Pott a disease, an aneurism, and a fracture. Jacob and Saemisch have ulcers, while Landry, Charcot, Gerlier, Kennedy, Parkinson, Erb, and Bell suffer from paralysis. Kopp and Millard are asthmatic. Westphal, Romberg, von Graefe, Möbius, Rosenbach, Parrot, and Guyon, all have symptoms. There are the laws of Boudin, Colles, Levert, and Stokes, as well as of the Medes and Persians. Paget has two diseases—one of the skin, the other of the bones. Hebra suffers from erythema, pityriasis, and prurigo. Duchenne is locomotor ataxic and has pseudo-hypertrophic paralysis. Cheyne-Stokes has uræmic respiration, and Argyll-Robertson a pupil. Hernia abounds. Astley Cooper, Cloquet, Béclard, Goyraud, Haselbach, Kronlein, Langier, Petit, Littre, Richter, and Velpeau have it in different forms. Hippocrates, Wels, and Corvisart, present a characteristic countenance. Huguier has uterine fibro-myomata, Thomsen a muscular spasm, and Volkmann a congenital dislocation. Basedow, Graves, and Parry are similarly afflicted with exophthalmic goitre. Boyer has a cyst, Gibbon a hydrocele, Dubini electric chorea, and G. de la Tourette motor inco-ordination with echolia and coprolalia. This is all rank and preposterous nonsense, yet so it is written. As far as the text is concerned there is no reason why it should not be believed.

The French, in whom taste and the sense of proportion are strongly developed, have begun a humble crusade against the foregoing pernicious practice of lumbersome and meaningless titles. The *Union Médicale du Nord-est* has a witty criticism on the subject, which is referred to at length in the *Gazette des Hôpitaux*, January 8, 1891. Language is a purely arbitrary thing, and as such demands infinite respect and countless efforts. Much mental confusion, ploughing around in bewilderment, retracing of steps, and the sad consciousness of time lost may be avoided by the use of words that are alive, words that would bleed if cut. Language is the test, the standard of mind. It is the gauge of difference between man and man, the measure of power and precision. Terms that refer to any exact science must be guarded as religiously as treasures of price, for false ideas rush in where words have no instructive value. Every one must be the debtor to his profession sufficiently to set his face resolutely against cumbersome nomenclature, and

resolve to call things by their right names, leaving the present senseless fashion of christening aches, pains, pathological processes and principles to die a natural death. The present method is unbusiness-like, inartistic, thoroughly rococo, and a great injustice to every one in search of facts. By systematic care in the use of words expressing abnormities now hiding behind the mask of a name belonging to some dying, dead, or living writer, a nearer view may be obtained, resulting in greater good to each and all concerned. To clear away rubbish is an occupation not without value. This particular form needs to be removed with all possible speed, to be seen no more upon the face of the earth, and remembered only as one of the vagaries of an epoch otherwise remarkable for progress and enlightened reason.

THE CURVE OF HEALTH.

Dr. Oliver Wendell Holmes has made a discovery. It is that of the law of the curve of health. "It is a mistake," he says, "to suppose that the normal state of health is represented by a straight horizontal line. Independently of the well-known causes which raise or depress the standard of vitality, there seem to be—I think I may venture to say there is—a rhythmic undulation in the flow of the vital force. The 'dynamo,' which furnishes the working powers of consciousness and action, has its annual, its monthly, its diurnal waves, even its momentary ripples, in the current it furnishes. There are greater and lesser curves in the movement of every day's life—a series of ascending and of descending movements, a periodicity depending on the very nature of the force at work in the living organism. Thus we have our good seasons and our bad seasons, our good days and our bad days, life climbing and descending in long or short undulations, which I have called the curve of health. From this fact spring a great proportion of the errors of medical practice. On it are based the delusions of the various shadowy systems which impose themselves on the ignorant and half-learned public as branches or 'schools' of science. A remedy taken at the time of the ascent in the curve of health is found successful. The same remedy taken while the curve is in its downward movement proves a failure. So long as this biological law exists, so long the charlatan will keep his hold on the ignorant public. So long as it exists, the wisest practitioner will be liable to deceive himself about the effect of what he calls, and loves to think are, his remedies."

The fact of the existence of the "curve" in question cannot be doubted; but Dr. Holmes exaggerates its importance and its amplitude and its constancy. In acute rheumatism, for example, the curve is quite knocked out, and the field is left very clear for salicylic acid. In ague and syphilis, in dysentery and pneumonia, the same may be said.

A person with a neuralgia or headache is, in time, perhaps, cured by his "curve," but who would deny the help meanwhile given by antipyrine. The curve of health in phthisis is a pretty steep decline, unless the geometrical disturbance is confronted with pure air and creosote.

The "brightique," no doubt, has his curve; but it, too, is all one way; the medical art can lessen its precipitance. We do not take so dark a view of therapeutics as was popular when Dr. Holmes said that if all the drugs of the Pharmacopœia were thrown into the sea it would be better for mankind but worse for the fishes. Matters have changed a good deal since that day. There is still an immense amount of useless drugging; but it is much less than it used to be. The nature of diseases, the action of remedies are understood vastly better than was formerly the case; and every few years something of positive advance continues to be made. Medicine is not in the year 1830.

THE USE OF EXTRA TITLES.

The use of extra and distinctive titles for medical men has always provoked discussion among those who have and those who have not the coveted appendages. The recent action of the Toledo Medical Association in resolving to dispense with all extra insignia of rank brings the general subject again to notice. While much can be said on both sides we confess ourselves in favor of such extra titles as guarantee the possession of extra knowledge or ability. It may sometimes be the question which is the greater, the man or his title, the officer or the office, the professor or the college, the surgeon or the hospital, and so on. Few men are so celebrated as to carry with their work the simple name as sufficient authority for *ex cathedra* statements. There are too few Hannibals, Cæsars, and Napoleons in our profession to make precedents in such a line. Consequently, when a man claims a right to speak from his experience, it is proper to prove his fitness by stating his position and title. But the latter must be distinctive, if it adds force to the arguments and statements of an author or teacher. We admit that such distinctions are invidious, but all distinctions are invidious. Because they are so, men are willing to work and struggle for them, and in so doing make themselves fit the positions when they attain them. We are well aware that the man of mere titles means nothing. Those of professor are in some quarters so common that it becomes a real distinction to be a high private. The fellowships to societies are too numerous to mention, while the medical air is literally swarming with buzzing dispensary assistants. There is a happy medium between the two extremes of magnifying an office or of abolishing it altogether. It becomes after all a matter of taste with each man when and how to name his titles. There is as much presumption sometimes in avoiding their use on the egotistical plea that the name itself is sufficient as there is in making the tail too heavy for the kite. At all events, we cannot legislate on taste or expediency in this matter, and we very much fear that the resolutions of the Toledo Medical Association will be whistled down the wind.

THE TETANUS POISON.

In our interest over the pathological work done by Koch and his German colleagues, the labors of the French bacteriologists are a little neglected. It should be remembered that if Koch is to be regarded in any wise as a father of bacteriology, Pasteur is the grandfather, and he and his pupils have done work which is historic in this field. The *Annales de l'Institut Pasteur* is the medium by which this work is put before the world, and its

issues rarely fail to contain the results of important observations.

Recently Drs. Vaillard and Vincent have published a paper upon the etiology and bacteriology of tetanus, which deserves attention. They describe, again, the specific organism of tetanus, and show that it is not this organism but a poison that it secretes which causes the phenomena of the disease. The poison in question only develops after the bacillus has grown for some time and reached the stage of spores; yet it is not the spores themselves that are poisonous. They further show that the poison is not a ptomaïne, or any substance which has the characters of an alkaloid or base. The experiments made by Vaillard and Vincent confirm the fact that the tetanus bacillus cannot grow in the human body without the presence of another micro-organism; in this respect resembling diphtheria. The disease is therefore, in a sense, one of mixed infection.

Such studies bring us nearer every day to the actual cause of infective disease, and with such knowledge a means of prevention or cure is only a matter of time.

A NEW BASE FOR DERMATOLOGICAL USES.

Dr. George T. Elliott has, with the help of a pharmacist, Mr. Lascar, devised a new base for dermatological preparations. The principal component is bassorin, one of the vegetable mucilages, this being united with water, glycerine, and dextrine. The compound is called bassorin paste, and it has, according to Dr. Elliott, many advantages over the gelatine base of Unna and other similar substances. It is, he says, perfectly neutral and non-irritating, produces no irritation whatever, and when used alone it acts simply as a protective to the skin. It does not become rancid, or decompose, or undergo change when kept for a length of time, unless it be exposed in an open vessel. When this is done it becomes dry and hard, but even then rubbing it up with a little water renders it again as serviceable as at first.

It is easy and simple in application, requiring only to be spread upon the skin with the finger or a brush. It dries in the space of a few minutes if so applied, adheres closely, does not rub off and soil the linen, but forms a flexible coat, which does not interfere with the movements of the body. When its removal is desired, the preparation can be washed off with a little water, or a damp cloth or sponge. It remains *in situ* without change for a variable length of time, depending upon the condition of the surface on which it has been applied.

With the bassorin paste almost any drug can be incorporated; those which exist in the form of powders, or in solid forms in any amount desired; the tars, ichthyol, and oily substances in smaller percentages, but sufficient for all practical purposes.

These properties possessed by the bassorin paste render it superior to ointments, for the reasons, among others, that it is difficult to keep the latter in constant contact with the diseased surface; that salves soil and stain the linen, and offer such other objectionable features as greasiness, risk of becoming rancid, etc., to say nothing of the discomfort entailed upon the patients using them. It is also of wider application than the collodions and traumaticins, owing to the irritation of the ether and chloroform contained in them, their contractile property, the limited extent of surface over which they can be applied, and the difficulty experienced in removing them when desired.

Dr. Elliott is enthusiastic over the new base, but as he has only tried it for about two months, it may be well to wait for further experiences before accepting all that is urged for it.

CONTAGIOUS DISEASES IN PUBLIC AND PRIVATE SCHOOLS.

Two cases of diphtheria of a malignant type were recently discovered in the family of the janitor of one of the large public schools of this city. One of the children died. In the meantime the scholars continued in their attendance, as the parents had not been notified. This has directed public attention to the question of janitors with families of children occupying portions of the public school buildings, and Dr. Edson, of the Board of Health, has taken up the matter. During the past year there have been brought to the notice of Dr. Edson no less than six instances of diphtheria among the children of janitors living in public schools, and as this gentleman holds some decided opinions about the advisability of this practice continuing, it is probable that some action may be taken to lessen the dangers incurred by the thousands of children who attend the city's institutions of learning. In this connection it is gratifying to note that, as the result of a communication to the Record of January 10th, by Dr. Charles W. Allen, calling attention to the prevalence of contagious diseases in the families of Russian pedagogues who maintain private schools in their dwelling apartments, the Board of Health has carried out an investigation which showed the condition of these tenement schools to be so bad that a number have already been ordered closed. The Board of Health has in contemplation an amendment of the Sanitary code which will do away with this danger, by limiting schools in tenements to those authorized by the Board. This action is most commendable, for the very thought of twenty to forty growing boys being crowded into a dark, dirty dwelling room where one of the teacher's children is sick with scarlet fever or diphtheria is most revolting, and at variance with our ideas of the fitness of things in this stage of our march toward a higher civilization. In the public school the pupils may not be much more exposed from the sickness in the janitor's apartments than if he lived next door, and the fact that no outbreak among them has as yet occurred in any of the instances mentioned would go to confirm such a view; still, none of us would care to send our children into a school building where such a dread disease as diphtheria was known to exist.

In the case of the tenement school the pupil is thrown into direct contact with the disease often for several days before its true nature is discovered, and from the reports of the unhygienic condition of these school-rooms it is a question whether any amount of disinfection can render them wholesome and free from subsequent danger. It would seem that the average public school building in New York is not a desirable place to bring up a family of children, if we can judge from the number of contagious diseases occurring in the janitors' quarters;

but whether this will prevent family men from accepting the positions and thus lead to a self-regulation of the matter, or whether the janitor of the future will be condemned to a life of celibacy remains to be determined. One thing, however, is sure, and that is that the tenement house school, as it now exists, is a danger to public health and a disgrace to the city, and the sooner the school and the teacher's family become separate institutions the better it will be.

FREQUENCY OF PLEURITIC ADHESIONS.

A SHORT article upon this subject in the "Annual Report of the Supervising Surgeon-General of the Marine Hospital Service for 1890," by Surgeon Banks, is well worthy of attention. Desiring to obtain an intelligent conception of the frequency with which pleuritic adhesions exist in persons who present no history of pleurisy, Surgeon Banks has made a careful search through the Marine Hospital necropsy records of the past ten years for statistics bearing upon this subject. In the ten years since 1881 he finds 1,356 complete necropsies in which mention is made specially of the state of the pleura, or in which it may be safely included in the general statement that "with the exception of those organs named, all other organs were healthy." Of these 1,356 necropsies, 527 were classed apart by themselves, 156 of them being on pneumonic, and 371 on tubercular patients. In the 371 cases in which the patients had died from tubercular or from acute or chronic pneumonic phthisis, pleuritic adhesions were found 279 times (seventy-five per cent.); and in the 156 cases in which death had resulted from acute pneumonitis, pleuritic adhesions were found 112 times (seventy-one per cent.)

Especial attention is directed to the remaining 829 necropsies, since they were done upon the bodies of patients who had died of disease not immediately affecting the pulmonary tissues and who had presented no history (according to the hospital records) of pleuritic disease. In 322 (forty per cent.) of these cases the necropsy revealed pleuritic adhesions, varying from local adhesive threads to complete union of the lung and chest wall, too firm to be broken.

The practical lesson which Surgeon Banks draws from these observations is that slight attacks of pleurisy must be very frequent, although they either pass unheeded or are mistaken for simple neuralgia. In all cases of persistent thoracic or costal pain, attended by a sense of discomfort upon deep inspiration, the physician should take into consideration a possible inflammation of the pleura and would do well to seek a definite diagnosis. This effort should be made at the first onset of the trouble, for in the simplest forms of pleuritis the characteristic friction-sound is heard only during the first two or three days, and although adhesions of considerable extent may form there may not be enough exudation to attract attention.

After adhesions have once formed we have no means of releasing the attached surfaces, unless a course of pulmonary gymnastics, as suggested by certain observers, can bring about such release in recent cases.

It is suggested that in cases in which percussion and auscultation fail to elicit dulness or to reveal disease-sounds, yet in which the inspiratory expansion is subnormal, there are probably loose fibrinous pleuritic adhesions present—the evidences of their formation and persistence having been either ignored or forgotten by the patient.

Although the subject of the diagnosis and treatment of pleurisy with adhesions is one of great difficulty, yet the intelligent physician will welcome even purely statistical information such as the paper furnishes, as affording an incentive to greater earnestness in clinical observation.

News of the Week.

Professor Tyndall has just recovered from an attack of insomnia, associated with phlebitis.

The Cantharidate-of-Potash Cure for Tuberculosis.—Professor Liebreich, of Berlin, is a chemist of acknowledged reputation; hence his assertion that he has a remedy which is useful in phthisis attracts some attention. All that we can learn is that the substance is cantharidate of potash, that it is used by hypodermic injection, and that it has been tested clinically by Drs. Fraenkel and Hoffmann, who confirm in a measure the claim for its remedial value. Meanwhile the French physicians are using goat's blood and dog's serum with excellent results; and we are not likely to be without a new phthisis cure for some months to come. Meanwhile the mortality from phthisis in this town continues to be about one hundred per week.

An Institute of Preventive Medicine.—Steps are being taken in London to found an Institute of Preventive Medicine, with the following objects: To provide a place in which researches may be carried on with a view of finding the means for preventing and curing infective diseases in man and the lower animals. To provide education in preventive mecicine for medical officers of health, veterinarians, etc. To treat persons suffering with infective diseases, or threatened with them. To found laboratories, libraries, etc. It is probable that the institute may be located in Cambridge.

Tuberculin.—In a discussion on Koch's curative lymph before the Association of Berlin Surgeons, February 9th, (*The Lancet*) Professor Sonnenberg showed a female patient who had been almost entirely cured of extensive lupus. She has been treated by Koch's method since October. She had been treated without success before by other methods. Professor Hahn said that he had found it advantageous to puncture the parts affected by lupus during the administration of Koch's fluid. Dr. James Israel reported a case of indubitable lupus, in which there was no local reaction whatever. Dr. Lindner, of the Augusta Hospital, has in most cases observed no reaction, either local or general, or hardly any, after the injection for lupus, but has, nevertheless, obtained favorable results. Professor Bardeleben declared it a great mistake to pronounce a final opinion upon Koch's method yet. Dr. Koerte, of the Hospital am Urban, stated that in most of his cases the morbid phenomena altered only a little under Koch's treatment; but he, too, has seen isolated cases of improvement. Dr. Bartels raised the question whether general miliary tuberculosis had been observed in patients

with surgical tuberculosis after Koch's injections. None of the surgeons present had seen any such effect. Professor Bardeleben said there was no doubt that general tuberculosis and tuberculous meningitis might set in during the application of Koch's method, but it was hard to say whether they were due to the injections.

Medical Books.—In 1889 about 133 new medical and surgical works emanated from the press, and 49 new editions of old or standard works. In 1890 the number ran up to 143 new works, and there were 50 new editions. On the other hand, theological, fictional, and historical literature show a marked decrease in the number of new volumes published.

The State Medical Societies begin their work next month, and the following are the dates: South Carolina Medical Association, April (date and place not known); Florida Medical Association, Pensacola, April 14th and 15th; Medical Society of the State of Tennessee, Nashville, April 14th, 15th, and 16th; Medical Association of the State of Alabama, Huntsville, April 14th, 15th, 16th, and 17th; Mississippi State Medical Association, Meridian, April 15th, 16th, and 17th; Medical Association of Georgia, Augusta, April 15th, 16th, and 17th; Iowa State Medical Society, Waterloo, April 15th, 16th, and 17th; Medical Society of the State of California, Sacramento, April 21st, 22d, and 23d; Medical Association of Montana, Helena, April 24th and 25th; Medical and Chirurgical Faculty of Maryland, Baltimore, April 28th, 29th, and 30th; Texas State Medical Association, Waco, April 28th, 29th, and 30th, and May 1st; State Medical Society of Arkansas, Hot Springs, April 29th and 30th, and May 1st.

A Republican's Point of View.—It is far easier to destroy than to construct. For the first time in a generation the Democratic party has control of the State of Michigan. As a result, it seems to have awakened from a Rip Van Winkle sleep, and proceeds to reduce public institutions to a condition suitable for thirty years ago. The State Board of Charities and Correction, the State Board of Health, etc., are marked for destruction, and the State has returned a long way toward an antiquated civilization.—*Peoria Medical Monthly.*

A Medical Hat.—Certain enthusiastic gentlemen have proposed that doctors distinguish themselves by wearing an olive-green button. An English doctor suggests in the *Lancet* that a special hat be adopted, and the suggestion is warmly received by a colleague, who writes: "It seems to me that the suggestion of your correspondent in today's issue, that medical men should wear a distinguishing hat, is one which commends itself to everybody. I would, however, suggest that as conspicuousness seems to be an object of your correspondent, it is a pity to adopt a hat with a low crown. Why not have one with a decided length of cylinder—let us say three feet long? It would be so readily discerned at a distance. Further, in order to render the doctor still more easily recognized, I would propose to have the tile painted sky-blue and varnished, or decorated in any other manner to suit the taste of the wearer, after the style of the gentlemen of the ring on the racecourse. And while on this subject, why limit oneself to a hat? A fancy dress or a Pickwickian costume would look picturesque, and, I am sure, would not fail to attract the attention of strangers and others who might be requiring the services of a medical man. The subject is one that is capable of vast extension, and I doubt not would be readily adopted if properly brought to the notice of the leading members of the profession."

Professor Dr. Edmund Hartnack, the eminent optician, is dead. He died at Potsdam, where his optical institute was. Before 1870 he lived in Paris, but, after the war broke out, he returned to Germany. He is believed to have been the first to introduce immersion into microscopy. His microscopes quickly obtained a European reputation, and it is not too much to say that indirectly we owe to him much of the progress of modern medicine. The University of Bonn made him Doctor *honoris causa* in 1868; the honorary title of "Professor" was conferred on him by the Government.

The "Bill to Regulate the Practice of Medicine and to create a Board of Medical Examiners in Texas," prepared by the Committee on Medical Legislation of the Texas State Medical Association, was introduced into the Texas Senate on February 14th, and was referred to the Committee on Public Health. It was reported upon favorably by the committee, and recommended for passage with an amendment striking out section 10, which relates to revoking licences for unprofessional conduct. It will go to the House shortly, and will, in all probability, become a law.—*Daniel's Texas Medical Journal.*

The Ice-Cradle to Reduce Temperature.—The ice-cradle is an arrangement by which a constant current of cool air can be brought into immediate contact with the surface of the body, and thus bring about a reduction in its temperature by direct abstraction of heat. This method was originally introduced by Dr. Samuel Fenwick as a substitute for the cold bath in the treatment of typhoid fever, and with this object it has now been used for many years in his wards at the London Hospital, with the most excellent results. It consists essentially of an iron surgical cradle, from the central bar of which are suspended several small zinc pails half-filled with ice. The patient lies undressed upon the bed, and the cradle, covered by a light counterpane, is placed over him. In order to prevent any feeling of chilliness a hot-water bottle is kept in contact with the patient's feet. The ice in the pails is renewed at intervals, and it is found convenient in practice to cover the bottom of the pails with a piece of lint in order to prevent any condensed moisture from dripping upon the body of the patient. In default of the iron cradle, a very good substitute can be easily made with a piece of strong wire, or from two wooden hoops sawn through the centre. Under such an arrangement a patient may lie for many days, the utmost required being to replenish the ice-pails, and occasionally to renew the hot-water bottle at the feet. Although the mean temperature of the cradle can rarely be reduced more than a degree or two below that of the surrounding atmosphere, it usually suffices to effect a reduction of several degrees in the temperature of the room and maintain it there.

Dr. John R. Howe, who had been one of the prominent physicians in Ontaria County, N. Y., for forty years, died at Phelps, N. Y., February 26th, aged seventy-one.

Death of Dr. Hosmer Allen Johnson, of Chicago.—Dr. Hosmer Allen Johnson, one of the oldest, as well as one of the ablest, practitioners of Chicago, died at his home in that city on February 26, 1891. For some weeks he had been in failing health, resulting finally in fatal heart decline. For nearly forty years Dr. Johnson had been prominently identified with medicine and surgery in the several capacities of practitioner, writer, instructor, and State official. He was instrumental in founding one college, taught in another, and his contributions to the medical press are many. He was characterized by a broad sense of the noble in professional ethics. Dr. Johnson was not a specialist, but had that wide learning which marked him all through life as a leader. He had a warm, generous heart, and a multitude of people loved him because of those kindlier qualities which do not always go hand-in-hand with professional distinction and learning.

The New Lunacy Bill.—A bill has been introduced in the New York Legislature to repeal the "State Care of the Insane" act, and to provide that every insane asylum shall have a board of twelve trustees and managers, seven men and five women, who shall be elected by the people of the city or town where the asylum is located, and who shall have entire control and management of such asylum. The passage of such a bill would be a step backward. The State Commission in Lunacy, which now has control of the asylums has brought about system in the methods of book-keeping, has raised the standard of medical attendance and nursing, has reduced the per capita cost of patients, and made many improvements which from time to time have been noted in the RECORD. The centralization of power works to advantage in all great systems, notably those of the Canals and Education, and it has proved of inestimable value in the administration of the affairs of the asylums. The argument against the establishment of boards of managers of twelve members each are innumerable. In the first place they are unwieldy, too large for efficiency; secondly, system and uniformity are entirely lost. The arguments for State care and not county care of the insane are so strong and so well known that few disinterested physicians favor the latter. The bill pending should and probably will fail in passage, and the profession should direct every effort to gain that disposal of it.

Medical Italian Senators. — Dr. Giulio Bizzozzero, Professor of General Pathology in the University of Turin, and Dr. Ottavio Morisani, Professor of Obstetrics in the University of Naples, have been named Senators of the Kingdom of Italy.

The Largest Dose of Tuberculin yet administered to a human being is four hundred milligrammes. It was given by mistake to a patient who should have received only forty milligrammes. The patient had phthisis complicated by intestinal tuberculosis, and had been under treatment for some time. The symptoms following the injection of this excessive dose were merely those of ordinary reaction of moderate intensity. Dr. Teleky, who reported the case at the last meeting of the Vienna Medical Society, stated that the reason why more severe symptoms were not observed was doubtless due to the fact of personal idiosyncrasy. The patient had never responded to the previous injections by high reaction temperatures, or other violent symptoms, and had developed considerable tolerance to the lymph. The next highest dose hitherto employed was that of two hundred and fifty milligrammes, which Dr. Koch used on his own person. In Dr. Teleky's case the physical signs of the patient were not materially altered by the enormous dose of lymph administered.

Cholera in the Russian North Pacific.—Cholera is still causing great ravages at Vladivostock on the Russian North Pacific coast, the Mansas and the Coreans being the chief victims. There seems to be an utter disregard of sanitary precautions, while such abuses as the casting of the dead into the bay still go on.

An Old Surgical Bill.—Dr. Charles E. Slocum, of Defiance, O., writes: "The Old Surgical Bill which was copied in the MEDICAL RECORD of February 14th has interested a goodly number of readers, as evidenced by the number of communications regarding it received by me. At this date the greater number prefer to read 'weuing the bodie' as viewing the body for the coroner, or as a form of coroner's inquest."

Section in Genito-Urinary Surgery of the New York Academy of Medicine.—A regular meeting of the Section was held on the evening of February 12th. Dr. R. W. Taylor was elected chairman, and Dr. Samuel Alexander, secretary. Dr. George H. Fox presented a case of papular syphilis in groups, and made some remarks upon the diagnosis of cutaneous syphilis which he illustrated by original photographs. Dr. R. W. Taylor reported three cases, viz., traumatic hyperplasia of the vulva; syphilitic hyperplasia of the vulva, and epithelioma of the penis not involving the glans. Water-color drawings of these lesions were shown. The following papers were read: "Report of a Case of Papillary Adeno-carcinoma of the Bladder, with some Observations upon the Diagnosis of Small Papillary Fibroma of the Bladder," by Samuel Alexander, M.D., and "The Contagiousness of Chronic Urethral Discharges," by George E. Brewer, M.D. These papers were discussed by Drs. Sturgis, Bangs, Bache-Emmet, Morrow, Brown, Otis, and Taylor. The next meeting of the Section will be held on Thursday evening, March 12th, at eight o'clock.

None but Bona-fide Diplomas Recognized.—The Illinois State Board of Health has decided that hereafter it will recognize no foreign diploma that does not confer upon its holder the right to practise medicine in the country in which it was granted. The holder of an Austrian, a German, Russian, or Swiss diploma, wishing to practise in Illinois, must hereafter pass an examination before the Board, unless he have a pass certificate from a Government examining commission. The holder of a Canadian diploma, unless a licentiate of the Colleges of Physicians and Surgeons of Ontario and Quebec, must pass an examination in order to be licensed in Illinois.

Dr. W. W. Dale, a leading physician of Southern Pennsylvania, died at Carlisle, February 26th, of pneumonia, aged seventy-four years. He was a member of the State and County Medical Societies.

Reviews and Notices of Books.

Transactions of the Gynecological Society of Boston. New Series. Vol. I. Cloth, pp. 396. Illustrated. Boston: Cupples & Hurd.

This Society was founded almost a quarter of a century ago. On its rolls are one hundred and three active and honorary members, and over six hundred corresponding members, including the brightest and most famous gynecologists in the world. Seven volumes of its "Transactions" (1869–72) have been published. So appreciated was their value that the several editions were long ago exhausted, and the volumes cannot now be obtained. They are frequently referred to in the works of gynecology issued in both hemispheres, and a considerable portion of the American cases quoted by the late Professor Schroeder, in vol. x. of "Ziemssen's Cyclopædia," are taken from the work. This new volume is equally as valuable as its predecessors. It is written, in large measure, by the same authors, prominent among whom is Dr. Henry O. Marcy, who was President of the Gynecological Section of the International Medical Congress held at Washington three years ago. He contributes an invaluable paper on "The Perineum, its Anatomy, Physiology, and Methods of Restoration after Injury." He not only clearly defines his own excellent operation, with illustrations, but gives a *résumé* of other accepted methods. He also writes of bacteria, which subject is further elucidated by Drs. Ernest W. Cushing and Samuel N. Nelson. That brilliant old veteran, Dr. Henry M. Field, gives his "Treatment of Constipation," and in another paper, on his "Errors," decries the use of the speculum, nitrate of silver, and the too frequent use of the uterine sound. Dr. J. Collins Warren, of Harvard, contributes an admirable paper on "Diagnosis and Treatment of Cancer of the Breast." Dr. W. Symington Brown treats of "Chronic Cystitis;" Dr. Moses D. Church, of "Post-Uterine Abscess;" William G. Wheeler, one of the founders of the Society, of "Septicæmia." "Abortion and Premature Labor" are discussed by Dr. J. E. Kelly and Dr. Elizabeth C. Keller. Dr. Kelly's paper caused wide discussion, and his suggestion to submit all cases of abortion to a board of medical men, specially appointed, received a great deal of attention. In the line of therapeutics, the volume contains articles on "Corrosive Sublimate and Ergot," by Dr. Charles W. Stevens; "Chloral," by Marshall L. Brown; and "Electricity," by Augustus P. Clarke. There is a good article on "Forceps," by Samuel N. Nelson; and Dr. Helen L. Betts, a bright, brainy woman, writes on "Dress" in a most interesting and instructive manner. There are other papers equally worthy of mention, twenty nine in all, making a book that is a valuable addition to any physician's library.

Description of the Johns Hopkins Hospital. By John S. Billings, M.D. Baltimore: Press of Isaac Friedenwald.

Eighteen years ago Johns Hopkins made one of the most munificent gifts to medicine that the science has ever known, namely, three and a half millions of dollars, for the building and support of a hospital in Baltimore. As Dr. Billings says, it was the donor's idea to provide proper care of the sick, both rich and poor; to provide for the highest class of medical education; to increase and diffuse knowledge; to provide trained nurses for both hospital and city; to provide a dispensary, and to make the buildings and grounds ornamental and attractive. It was to compare favorably with any other institution of like character in this country or in Europe. After Mr. Hopkins's death the trustees named in the will selected five famous men, skilled in hospital lore, to give their ideas of a perfect hospital. The great hospitals of the East were visited and inspected; one of the essayists was sent abroad, and then, with the aid of an architect, the suggestions and plans thus gained were formulated, and the ideal hospital placed on paper. Unlimited resources carried out these plans, and to-day there stands in the eastern part of Baltimore a hospital which has no superior, and few, if any, equals in the world. In every respect—beauty, utility, drainage, ventilation, comfort, etc.—it is perfectly equipped. It would be interesting and instructive to know the exact cost of these buildings. We think the trustees are hardly justified in the secrecy maintained on this point. This volume, by Dr. Billings, gives its history from its conception to its completion, with a minute description of its every detail. It is superbly printed, a model of typographical art, the plates of which there are fifty-six, being especially worthy of unstinted praise. As a contribution to the literature of hospital construction the work cannot be overestimated. It will be of immense value to builders of hospitals in the future, and in the present is of interest to every educated man, whether he be in the medical profession or not. The book also contains Dr. Billings's dedicatory address, which is written in his usual bright, forcible style.

Progressive Exercises in Practical Chemistry. By Henry Leffman, M.D., Ph.D., and William Beam, M.A. Pocket note-book size, 102 pages. Philadelphia: P. Blakiston, Son & Co. 1890.

This manual includes the methods of laboratory instruction as given in recent years in two of the medical institutions with which the authors are connected. It contains a general description of apparatus and manipulation, followed by an outline of general chemical principles. Then come exercises in the chemistry of the important elements. It is an excellent aid to the home study of chemistry, and written in good, intelligible English.

Rheumatism and Gout. By F. Le Roy Satterlee, M.D., Professor of Materia Medica, New York College of Dentistry, etc. Pp. 84. Detroit: George S. Davis. 1890.

It is always interesting to read the opinions of a practitioner on the old and common maladies. The writer informs us that he himself was a sufferer from an inherited rheumatic and gouty dyscrasia, and was thus led to a close study of these two diseases. His views on pathology are orthodox, and he accepts the uric-acid theory of causation, but is willing, also, to admit that there may be added the influence of some specific germ yet to be demonstrated. It is in the sections on treatment that we notice most strongly his individual views. In acute rheumatism he gives alkalies up to the point of saturating the system. He "does not approve of, or recommend, the employment of salicylic acid or the salicylates." These remedies may relieve the pain promptly, but they are uncertain, transient, and depressing to a dangerous degree. For the fever antipyrine and its congeners are strongly urged, and the suggestion is made to add one-half a grain of powdered digitalis to each dose thereof. In acute gout, again, he protests against the use of any form of colchicum. Patients soon learn to use it themselves, and he regards many of the sudden deaths among the older wealthy classes, occurring from so-called "heart failure," as really due to the improper use of colchicum. Its effects are transient, and its depressing action on circulation, digestion, and muscular tone render it a dangerous remedy. Alkaline treatment is the one recommended, with a judicious use of cholagogues. Euonymin seems to hold a high place in the writer's regard.

Saunders's Medical Lexicon. By John M. Keating M.D. Philadelphia: W. B. Saunders. 1890.

A vest-pocket lexicon with brief yet complete definitions, and a valuable list of etymological factors common in medical terminology. It is brought down to the very latest nomenclature in even the newest departments of medicine, and is a credit to both author and publisher.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Meeting of January 12, 1891.

ROBERT ABBE, M.D., CHAIRMAN.

Election of Officers.—DR. WILLIAM T. BULL was elected Chairman, and DR. CHARLES A. POWERS, Secretary, for the ensuing year.

Removal of the Hypertrophied Median Lobe of the Prostate.—DR. R. F. WEIR presented a man, aged fifty-seven, on whom he had performed supra-pubic cystotomy for vesical stone, and through the opening thus made also removed the hypertrophied median lobe of the prostate. The man had had to use a catheter for seven years, and six months previously the end of the instrument, which had become swollen and brittle from use, broke off in the bladder, and formed the nucleus of a stone of considerable size. The man made a satisfactory recovery from the operation; in four weeks the supra-pubic wound had closed, the urine passed through the natural channel without the aid of a catheter. The amount of residual urine did not exceed two drachms.

There was considerable oozing where the median lobe of the prostate had been cut away with the curved scissors, and it was not completely controlled until iodoform gauze had been introduced. This was left in twenty-four hours, and not only checked hemorrhage, but seemed to disinfect and keep the bladder sweet. He remarked that removal of the prostatic obstruction was proper only where the changes in the kidney had not advanced far. The use of the scissors in removing the enlarged lobe had not proved satisfactory, and he proposed to use Mackenzie's tonsillitome on the next occasion.

Trephining for Traumatic Epilepsy—Re-implantation of Bone.—Dr. Weir presented a second patient, a man, aged fifty-three, who had sustained an injury of the forehead when seventeen years of age from the explosion of a musket. The injury left a depressed portion just above the right eyebrow. Epileptic seizures appeared and progressed until their recurrence was as often as five times a day. In 1885 Dr. Weir trephined over the depressed portion of bone, removing a piece which had a knuckle on its interior surface. It was smooth, non-adherent to the dura mater, but encroached on the cranial cavity. The operation relieved him to a certain extent, but it was difficult to say how much, since almost all epileptics were relieved in some degree for a time following such operations. The attacks having recurred in 1887, Dr. Seguin saw the patient with him, and although, as might be expected, there were no muscular group symptoms, they decided, in the light of recent cerebral surgery, to perform a second operation. A longer opening was made, extending upward, the dura was cut, and the brain examined carefully, but nothing was found further than a strong adhesion between the dura and pia near the original opening. The three disks of bone were replaced and the interspaces filled in with bone chips. The wound healed favorably, and the man had subsequently only from one to three epileptic attacks a month. He was able to attend to his business fairly well. The speaker thought that, as a rule, we could hope to get improvement from trephining for epilepsy, especially in cases of idiopathic local character, but seldom did an entire cure take place. Since the last time he had seen this patient a pulsation had become visible about the original seat of injury, showing that the re implanted bone at that point had become absorbed. It was the rule for a depression to form where the bone had been re-implanted. He had feared irritation might result from the slight asperities on the re-implanted chips of bone, but this had not been the case, and doubtless the asperities had become absorbed.

Dr. Weir said that in 1887 he trephined and removed an infiltrating sarcoma of the brain, and, as was expected, rapid recurrence took place; but owing to the freedom for expansion allowed by the cranial opening, the man was in much better condition for some time, and death did not finally take place until three years after the operation. He had advocated trephining, without replacement of the bone disks, for pressure symptoms, since 1886. Through the opening further exploration could subsequently be made if indicated.

Permanent Supra-pubic Drainage.—DR. WILLY MEYER, in opening the discussion on Dr. Weir's first case, presented a man, fifty-eight years of age, on whom he had operated in the summer of 1889 by supra-pubic cystotomy. The patient had had trouble with urination for eight years, and one night when Dr. Meyer was first called to see him he was suffering from complete urinary obstruction, demanding supra-pubic puncture. Thinking from the symptoms that there might be a bladder tumor or stone, he shortly afterward performed supra-pubic cystotomy, and at the same time removed the enlarged median lobe of the prostate. The lateral lobes were also very large. Suspecting pyonephrosis, he thought it best not to close the supra pubic opening, and thus avoid possible injurious consequences from residual urine. The urine was conducted out of the bladder through a soft-rubber tube passing through the supra-pubic fistula, held in place by aid of a hard-rubber plate which it penetrated. By lowering the outer end of the tube and taking out the cork the urine was caused to flow. None escaped around the tube at the point where it penetrated the abdominal walls. The patient had remained healthy and comfortable since the operation in 1889.

An Extemporized Method of Supra-pubic Drainage.—DR. A. P. GERSTER said that where a special instrument could not be procured for draining the bladder, one could puncture above the pubes with the trocar, leave the trocar cannula in until an elliptic-shaped fistula formed, then introduce a soft catheter and fix by safety-pin and adhesive plaster. He had seen the method work well, without leakage taking place. Some degree of judgment must be used in selecting cases suitable for removal of the obstructing median lobe of the prostate. If the bladder had lost its contractile power, all the urine would not be expelled, even after complete removal of the obstruction. The method of packing the bladder with iodoform gauze, mentioned by Dr. Weir, was a well-established one. The hemorrhage was checked by it not so much from pressure as from the coagulated mass which promptly became interwoven with it.

Maniacal Insanity relieved by Trephining.—The CHAIRMAN said, with regard to Dr. Weir's second case, that it suggested the propriety of repeated trephinings for epileptic and mental symptoms. In the case of a boy with symptoms approaching maniacal insanity he had given relief for six months after trephining, and he now thought a second trephining, after return of the symptoms, might afford renewed relief.

Prefers the Chisel to the Trephine.—DR. GERSTER thought it was not uncommon for the dura mater to be injured by the trephine. He now used the chisel only, and believed it was destined to entirely replace the trephine, as it had in operations on the mastoid process. He had found that the chips could be successfully replaced. He emphasized the point made by Dr. Weir, that the button, in certain cases, should not be replaced, thus obviating intra-cranial pressure and permitting of subsequent exploration. In trephining in one case of Jacksonian epilepsy he had not replaced the button, thus leaving the dura free to expand and giving a chance for future local treatment if thought desirable. Thus far the seizures had ceased.

DR. WEIR said he had seen no ill effect from injuries to the dura mater with the trephine. He had seen the chisel used and impinge so strongly upon the dura as to do as much harm as could result from the trephine. In

short, he did not think the chisel had great advantages over the trephine.

Cholecystotomy for Biliary Calculi.—Dr. A. G. Gerster then presented a married woman, thirty-one years of age, who first had an attack, apparently of biliary colic, three years ago. She had had two or more attacks since. When he saw her, in consultation, after an attack, a small "lump" could be felt in the right hypochondriac region, which was very sensitive to the touch. Besides three severe seizures, there was almost continuous slighter pain in this region. No jaundice; appetite good. Dr. Gerster advised an exploratory incision, having first made a diagnosis of distention of the gall-bladder. An incision was made, parallel with the lower border of the ribs, a distance of three or four inches, and on reaching the peritoneum, a rounded tumor bulged up which was recognized as the gall-bladder. Two silk sutures were put into the wall of the tumor, by which it was drawn into the aperture and stitched to the parietal peritoneum all round. The gall-bladder was then incised, and he was surprised to find the walls nearly an inch thick. A considerable quantity of very dark bile escaped, but the presence of stones did not become evident until the opening had been dilated. Sixty-six small stones were removed which had facets. A probe was introduced a distance of three inches into the cystic duct before it came in contact with a stone. This stone had been felt by palpation before the gall-bladder had been opened. It was fully an inch in diameter, and considerable difficulty was experienced in removing it. Finally he dilated the duct sufficiently, and caught the stone with a pair of forceps and removed it. No more stones could be felt, and he dressed the wound in the usual fashion, and introduced a drainage-tube. The patient did well, but continued to have constant pain in the region of the gall-bladder, and over two weeks after the operation the probe passed into the wound left by the drainage-tube came in contact with a stone. The aperture was dilated with a cupola tent, and three more stones were removed. They had apparently been in the cystic duct previously. She was discharged cured about four weeks later, but afterward had further pain, and Dr. Gerster being disposed to think this due to stone in the cystic duct, advised massage. This was practised two or three weeks, after which the pain ceased. The general condition of the patient had since improved very much.

Dr. Weir, in commenting upon these cases, cited one which showed that the stone could be dislodged by massage as Dr. Gerster had suggested, and also stated that the common duct could readily be explored by the steel sound, No. 8 or 10.

Dr. B. F. Curtis said that, eighteen months ago, he had operated upon a case which showed the objection to suturing the gall-bladder to the parietal wound before incising it. The case was also interesting as illustrating the difficulties in the way of diagnosis. The liver was displaced so far downward that it was supposed to be the large intestine full of fæces, while the distended gall-bladder was supposed to be a perityphlitic abscess. Exploratory incision revealed the liver and gall-bladder, and he sewed the latter into the wound and opened it the following day. A large stone could be felt near the cystic duct, but it could not be removed. Failing, a week later, to remove the stone, they put the patient under ether, and after many attempts succeeded in removing one stone, when they felt still another impacted in the cystic duct. He made an incision in the median line parallel to the first, and then, with the little finger in the abdominal cavity, and instruments in the gall-bladder, they succeeded in crushing and removing the stone. It had been adherent over nearly its entire surface to the mucous membrane, which made it impossible of removal until it had been crushed. He thought that if, at his first operation, he had gone on to incise the gall-bladder and remove the stones, the patient would have been subjected to less risk, for at the second operation he had to make a fresh opening and expose the peritoneum to discharges from the previously made and granulating wound. The patient, however, made a good recovery.

The Chairman said, regarding the great hypertrophy of the walls of the gall-bladder in Dr. Weir's case, that two years ago he had a case in which they were so thick that they suspected cancer. After the operation, however, the hyperplasia disappeared until no tumor could be felt.

Total Extirpation of the Larynx—Artificial Larynx.—Dr. Willy Meyer related the case and presented the patient.

Simple Apparatus for Permanent Supra-pubic Drainage.—Dr. L. B. Bangs presented the instrument, which consisted of a hard-rubber plate moulded by dipping into hot water to snugly fit the abdomen. Under it was a felt plate, which the patient found pleasant to the feel, and could renew with very little expense. Through these the tube or catheter passed into the bladder. The tube could be renewed at little expense independent of the plate.

Luxation of the Patella.—Dr. W. R. Townsend presented a negro girl, of about seventeen years of age, who by muscular contraction could dislocate the patella outward and replace it. Before treatment by fixation she had been able to dislocate it within also. It did not pass beyond the condyles. The parents said it had occurred from their earliest recollection, and was probably a congenital peculiarity. It had given her some trouble, especially as a child, when starting to run. Such cases were rare.

Recurring Luxation of the Lower Jaw.—Dr. Townsend also presented a woman, fifty-three years of age, who had been much troubled by recurring dislocation of the lower jaw since about five years ago, when a dentist used some force in taking a cast of the upper jaw. She could now keep the jaws in normal apposition only by holding the mouth shut, and during sleep the lower jaw would slip forward.

Dr. Ridlon said he had seen two cases of voluntary dislocation of the patella in the service of Thomas, of Liverpool, one of which had been cured by hammering the outer condyle with a wooden mallet, setting up a bony exostosis which prevented the patella from sliding outward.

Dr. Kammerer said he had presented to one of the city medical societies an aged woman who had complete congenial dislocation of the patella outward *over* the condyle. She could not produce the displacement voluntarily.

Dr. Ketch had seen only one case which properly came under this class, a boy, who had unilateral dislocation of the patella, together with genu-valgum. Usually the dislocation was bilateral.

Dr. C. A. Powers thought the trouble in treating luxations of the jaw successfully was the same as that which applied to dislocations of the shoulder, the member was not fixed long enough after reduction. He thought that in this woman's case the jaw had probably been dislocated while the dentist was putting in the plate, and he replaced it without her knowing it, and afterward she did not keep her jaw still.

Refracture of the Radius.—Dr. B. F. Curtis presented a young man who, fifty-five days after treatment for Colles's fracture of the radius by Dr. Powers, had a refracture brought about by exertion in trying to save himself from a fall while climbing a ladder. The amount of callus from the double injury was not very great; the functional result was good. Refracture was very rare, and only three cases out of forty-five, which he referred to, had occurred in the bones of the forearm. Another interesting fact in the case was that the refracture had been produced simply by traction.

Dr. Powers thought it very difficult to refracture the bones of the radius after four or five weeks. The only case of Colles's refracture which he had seen had been in a man with a distinct syphilitic history, and he attributed it there to syphilitic softening.

Spring Speculum for Overcoming Anchylosis of the Lower Jaw.—Dr. Powers presented a spring speculum, the jaws of which were separated by loosening a screw, for insertion between the jaws in fibrous anchylosis. It was less uncomfortable to the patient than the springless instrument usually employed, and gradually overcame the fibrous anchylosis. He had treated three cases, two of which seemed to have arisen from fixation long continued through irritation of the fifth nerve.

On retiring from the chairmanship, Dr. Abbe made some remarks on the successful meetings held by this Section, which he attributed to presentation of interesting clinical cases with condensed histories.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE MORPHOLOGY, CULTIVATION, AND TOXIC PRODUCTS OF TUBERCLE BACILLI—EXPERIMENTS ON ANIMALS—DEBATE ON ANGINA PECTORIS AT THE MEDICAL SOCIETY.

London, February 14, 1891.

At the last meeting of the Pathological Society Professor Crookshank read an interesting paper in which he gave an account of some researches he had made on the morphology, cultivation, and toxic products of the bacilli of tuberculosis. Stimulated, he said, by Koch's announcement at the Berlin Congress, he had cultivated the bacillus in liquid media, and later prepared cultures in milk, from which the bacilli were separated by filtration through porcelain. The filtrate was perfectly transparent, alkaline in reaction, and yellowish-brown in color. It was evaporated over sulphuric acid in a vacuum at a low temperature; this process occupied five weeks. The filtrate was then reduced to a brownish, viscous residue consisting chiefly of the glycerine in the original culture fluid. This extract proved to be extremely toxic. Two minims of the diluted extract produced in a guinea-pig a rapid fall of temperature, erect coat, periodic irregularity of the heart's action, irregular muscular spasms, loss of control over the extremities, and finally, death. Professor Crookshank said he concluded that the tubercle bacillus produced a complex proteid poison in which, as in anthrax, the alkaloid of tubercle or tuberculine was in a nascent condition. According to the stage of cultivation there would be a complex proteid substance, or this substance with free ptomaine, or ptomaine alone. Another line of inquiry was to obtain an extract from the tuberculous glands of cows suffering from perlsucht. The filtrate gave similar reactions to extracts of artificial cultivations of the bacillus.

Dr. Abraham and Professor Crookshank then made a joint communication on the effect of Koch's treatment on tuberculous guinea pigs. Similar phenomena were produced to those observed in the human tubercular subject. A cow suspected of being tubercular was also injected on two occasions with doses of 2 and 3 ctgr. The temperature was taken every hour, and was found to remain normal. Increased cough, however, was observed for some hours afterward.

Dr. Abraham stated that in consequence of the alarmist reports as to the dissemination of bacilli in patients under the Koch treatment he had lately examined the blood of two guinea-pigs before and during reaction. He had also examined the blood of ten human patients now undergoing the treatment—in some cases before, and also during and after the reaction. In no single instance had he been able to detect any bacilli, and he therefore thought that if any such metastasis took place as that indicated by Dr. Liebmann's observations it was certainly not of common occurrence.

Dr. Sidney Martin said the selection of proper cultivating media was a matter of much importance. Substances like glycerine, glycerine agar-agar, and glycerine broth were not met with in the body, and one was apt to go wrong if these were used as media. Glycerine, in fact, was not necessary at all, and an exuberant cultivation could be obtained if alkali-albumen were used with an amount of salts added in proportion to those of serum. It was not necessary to use any other products than those found in the body, and alkali-albumen was the nearest approach to a natural medium that could be sterilized and handled with convenience. The bacilli seemed to produce their poisonous products almost entirely from the proteids, the carbohydrates and hydrocarbons being apparently unacted on. Were we on the road to forming any generalization as to the production of these bodies from the proteids? He thought we were. Ordinary digestion produced albumoses, and, if carried a stage further by artificial digestion, pepto-toxin, a basic body of definite chemical formula, would be formed. So the anthrax bacillus formed not only albumoses but a specific alkaloid which could be isolated and which produced the symptoms of anthrax. Dr. Martin thought it would be found that all virulent organisms would similarly produce not only albumoses but an alkaloidal poison which was lethal if injected in large doses. He was not convinced that the chemical reactions obtained by Professor Crookshank proved that an alkaloid was present. All the albumoses were of interest. Anthrax albumose produced fever, but so also did the peptic albumose formed in ordinary digestion. The fever produced by the injection of Koch's fluid was like that produced by the injection of a large dose of peptic albumose into animals, and this latter might be accompanied by coma in the animal, just as coma had followed some of Koch's injections into human beings.

Dr. W. J. Collins, after referring to the classical experience of Buchner with bacillus subtilis and bacillus anthracis, said he thought the position with regard to bacteria would become considerably modified, and that it might be that their action was comparable to that of the unorganized ferments of the body.

An important debate on angina pectoris was initiated at the Medical Society on Monday evening last. Dr. Douglas Powell was the first speaker, and urged that the malady was not so simple a one as had been supposed. The characteristic symptoms ranged between the wide limits of remediable functional disorder on the one hand and fatal organic lesion of the cardio-vascular system on the other. He agreed with Dr. Broadbent that some cases of fatal cramp while bathing were probably due to sudden oppression of the heart from contraction of systemic arterioles—in fact, to vasomotor angina of an intense kind, associated, perhaps, with a fatigued heart. Though physiologists maintained that when the systemic arterioles were contracted by cold the visceral were dilated, and *vice versa*, yet it was highly probable that under certain conditions of chill and emotion the whole arterial system might undergo contraction. He quoted cases which seemed to show that the right side of the heart had borne the brunt of the anginal attack. The cardiac distress and rigid arteries of uræmia might, he said, almost be described as chronic persistent angina, though it was with the so-called cases of cardiac asthma in uræmia that the analogy with vasomotor angina was most obvious. Passing on to discuss angina pectoris gravior, in which the vasomotor disturbance was associated with degenerative cardiac disease, he criticised the view that the disease was necessarily caused by, or associated with, disease of the coronary arteries. The prognosis in the first group was comparatively favorable, the probability being that death would occur from some other cause, such as cerebral hæmorrhage, while in the last group an almost certainly fatal termination might be expected early. Both for prognosis and treatment it was important to make out the precise condition of the heart in respect of size, position, and power. Nitrite of amyl and nitroglycerine were of great value in treatment, but especially in the

graver cardiac cases. In the first group they required to be associated with nervine tonics and sedatives, while in the second group carminatives and stimulants were of special value. He compared the pain in cases of sudden death from angina to that associated with embolic gangrene of the limbs. He described a syncopal form of angina which was rarely met with except in persons over sixty-five, and then usually in association with gout; he suggested that undue acidity of the blood might be concerned in its causation. In conclusion, Dr. Powell said he regarded angina as a disturbed innervation of the heart and vessels associated with more or less intense cardiac pain and distress, and a general prostration of the forces, always producing anxiety, and often amounting to a sense of impending death. He grouped the varieties as angina pectoris vasomotoria, angina pectoris gravior, primary cardiac angina, and syncopal angina. Of these, the first two bore a remarkable resemblance to the respiratory analogue, asthma.

Dr. Ord insisted on the remarkable parallel between the symptoms of asthma and those of angina pectoris. He pointed out that the term asthma formerly comprehended a great many varieties of difficulty of breathing, and statisticians had shown that in times past asthma was a very fatal disease, according to the returns, any reduction in this respect being probably due to better diagnosis. With regard to angina, however, the range was wider than formerly, especially if Dr. Powell's conclusions were adopted. The old limited definition would have to be extended to a large number of cases in which one or two only of the constituent typical symptoms of the disease, as first described, would be present. Such cases might, perhaps, be described as anginous, if not anginal. These anginous attacks usually came on in the daytime, and the prognosis was notably aggravated when they supervened at night. He compared the two classes of cases, one in which the patient had angina on exertion as the consequence of sudden arterial tension caused thereby, and the other in which the attack occurred independently of muscular exertion, and in these he thought the mechanism was probably nervous, either emotionally or by reflex. He had seen illustrations of both classes. Dyspepsia was an important factor in bringing about the attacks, and he observed that if he were restricted to one remedy in the treatment of angina, he would prefer sulphate of magnesia to nitroglycerine, in order to secure a regular action of the bowels. Dr. Ord referred to the association of angina with glycosuria and gout respectively.

Dr. Broadbent said he had been unable to make up his mind as to the condition of the heart during the paroxysms. The pulse varied in different cases and was sometimes unaffected. The central fact was that the heart was overwrought either by peripheral resistance or on account of intrinsic failure. It was especially in those cases due to weakness of the heart that the great danger lay. Vasomotor resistance alone would not be sufficient to determine an attack. The proportion of cases of high arterial tension without angina pectoris was very much greater than the proportion of fatal cases of angina in which there was no disease of the coronary arteries. He presumed that disease of the coronary arteries acted by causing degeneration of the cardiac muscular fibres. With reference to the neurotic theory he pointed out that the vast majority of cases occurred in the non-neurotic sex. He ascribed angina in gouty people to its association with high arterial tension. He had also noted the existence of a myocarditis in patients suffering from glycosuria, associated with high arterial tension, and this was usually followed by marked anginal paroxysms. Angina was seldom associated with mitral lesions, and anginal symptoms usually subsided on the supervention of a mitral lesion in a person subject to anginal attacks. His own experience was that the gravest cases of angina were those in which the least explanation could be found to account for the symptoms.

The debate is to be resumed on February 23d.

SHALL M.D. BE A SUFFICIENT TITLE?

To the Editor of the Medical Record.

Sir: One of the inalienable rights of a citizen of this country is to "resolve," and if the citizen is a member of a medical society, nothing can prevent him from introducing resolutions into the society.

A real active resolution man does not lie awake nights over the defeat of any single resolution, but no sooner does he see one resolution shelved than another begins to take shape in his evolving mind.

In the Toledo Medical Association there is a pronounced dislike to resolutions; so much so that on the death of a member, scarcely more than one brief, "Whereas," and a feeble "Resolve," are ever permitted. Not so much, or at all, because the departed one had no friends, but because of the disfavor in which resolutions are held.

The real rub in the disposal of resolutions comes in when one member hates the resolution for one reason, and another member for something else.

One man may say that the resolution has a string tied to it, and that if the string is pulled, the resolution will do this, while another member does not believe that the thing is loaded at all, and were it not for the solicitations of the other member to the contrary, he would proceed to pound the life out of it.

In such a case it is difficult to decide whether it is the resolution or the members that are between the "—— and the deep blue sea."

Here is the last one that the Toledo Medical Association has had to deal with:

"*Whereas*, It has become customary for physicians to place after their names not only their professional titles, but also the names of medical societies to which they have belonged, and the names of those societies of which they are members; the official positions in those societies which they have occupied, or which they at present hold; the political office which they fill, or to which they were one time elected; the business positions which they have secured; the names of hospitals which they visit; the names of the medical colleges in which they are professors, lecturers, or assistants; and many other such titles, and,

"*Whereas*, Such an array of titles in no degree adds to the value of the paper at the heading of which they are placed, and,

"*Whereas*, Such practice savors of unprofessional advertising, and in that degree is undignified,

"*Resolved*, That we regard the mention of these titles, excep tthat of M.D., as unnecessary, and liable to suggest invidious distinctions, and therefore we advise their discontinuance for the future."

A little ripple in the deep running stream of thought that is "going on forever," in this Association is noticeable on account of this preamble and resolution.

You will notice that in the resolution all of the sharp corners have been rounded off, and that otherwise dangerous wires have been insulated, so that it is about as harmless as a resolution can well be, which fact and the season of the year tend to reduce friction and to keep the temperature down, so that you do not hear anybody calling someone else "another," nor anything of the kind.

It is not claimed by those who feel like giving them a kick, that the preamble does not amble along pretty close to the lines of truth and fact, nor that the resolution does not contain at least a small dose of needed medicine; but each one afflicted with the trouble says that he got it from some great man, and that others have it a good deal worse than he has, and that there is no use in trying to cure the disease in the Toledo Medical Association, when the American Medical Association is sending out the contagium in its most virulent form.

It is said that the mother association being affected in the same way, actually forces the thing upon us, and that such resolutions must originate in the parent association; rather favoring, you see, quarantine against the American

Medical Association. He would give it up in a minute if everybody else would do the same thing, but here is a way of "getting before the public" for all that a man is worth, and competition is brisk.

The resolution is in the hands of the Executive Committee and may never be heard of again, it may be defeated and it may be adopted, but we want to say to all post-graduate medical colleges and polyclinics, that if it survives, and the theme of the resolution becomes popular (?), and so starts "thundering down the ages," that no priority claim set up by them that they "first thought of it" will count as against this record. If you care to turn to the pages of the *Journal of the American Medical Association* you will find that one physician in every three whose articles appear in that journal contents himself by placing simply M.D. after his name. The other two make use of every conceivable title between "Professor," and "etc."

Imagine yourself being introduced to one of these great men, and as you stand grasping his hand have the one introducing you repeat his list of titles; why sir, you would feel before he had gotten half through as if you had had La Grippe for a week.

It is not uncommon to find in journals such puzzling things as a professor of orthopedic surgery reporting a case of pneumonia. Some day when you are feeling real well in mind and body just try to think of orthopedic surgery and pneumonia at the same time, and note how soon a feeling of "goneness" comes over you.

Now it is a fact that we haven't it as bad as that here. To be sure we have clinics, and retreats, and such things that you never heard of, and we admit that we work them for all there is in them, but — and we come around out of the same hole that we went in at, which is, that "others do it."

Long live professional (?) advertising!

Toledo, O. A. M.

THE TREATMENT OF INOPERABLE MALIGNANT GROWTHS BY THE ANILINE DYES.

To the Editor of the Medical Record.

Sir: In your issue of February 21st you published a note: "A New Cure for Cancer. Professor Mosetig, of Vienna, announces that in pyoktanin or methyl-violet he has found a remedy for cancer. He does not assert that any cases are quite cured yet; but the results have been so satisfactory as to lead him to think a cure will be found in the aniline dyes." I think the announcement may perhaps be of interest to many of your readers that since nearly eight weeks I have tried fuchsin one-half per cent. (alcoholic solution and ointment), in a number of patients suffering from inoperable ulcerated epithelioma of the face and scalp (rodent ulcer), at the Country Branch of the New York Skin and Cancer Hospital at Fordham Heights. The experiments were started in these cases by the suggestion of Dr. Amos C. Lewis, the Medical Superintendent of the Country Branch, on January 6th.

The results are partially marvellous, and so encouraging that I venture to send to you already this preliminary note for publication. Perhaps my observation will induce others to try this "dyeing treatment" in hopeless cases.

One of my patients, a man seventy-one years of age, in whom an aggressive growth has in reality been checked in its further spreading by a continuous application of fuchsine, was presented by me to the New York Surgical Society on February 25th, and to the Scientific Society of German Physicians on February 27th.

Since February 20th I am using pyoktanin (Stilling-Merck) in parenchymatous injections (1 to 300; 1 to 1½ drachm every second or third day) in inoperable cancer cases, according to v. Mosetig, giving besides, the same drug or methylin blue internally.

Yours very truly,

New York. Willy Meyer, M.D.

MORE ABOUT THE DISPENSARIES.

To the Editor of the Medical Record.

Sir: In your columns of February 21st the author of the communication "From Another Point of View" evidently implies that the dispensary offers no disadvantage in the way of success to the young practitioner, for he advises those who feel themselves unable to cope with what he terms "the modern essential of city life" to seek other localities. He seems to bring forward as an argument the statement that since only seven millions of people in the United States seek advice and treatment at free dispensaries, there is ample opportunity for every physician to succeed among the other fifty-five millions. I will allow that only one-eighth of our people are recipients of free treatment every year; but is this proportion not small in those cities where free dispensaries do exist? Why, in the city of Boston alone, which contains fully 450,000 people, last year 130,000, more than one-fourth of the entire population, enjoyed the privileges of our hospitals! and it would not be far from the truth to say that every year at least one-third of the invalid population of our city seek and obtain treatment in our hospitals.

However, the question is not whether our young practitioners shall remain in the city to cope with the outpatient departments or go to some country town, but, shall not something be done to limit the privileges of our institutions to the needy and deserving poor? The fact remains, nevertheless, that the objects for which our hospitals were founded are in many instances transgressed, when patients are treated who can well afford to pay the ordinary medical fee. In almost every city the regular is surrounded on all sides by quacks of every description, not to speak of patent-medicine mongers, and no matter what field "the intelligent, honest, and competent physician" may select, he has a right to expect and receive mercy and consideration from his brothers, whose duty it is to bestow them.

Very truly yours,

J. M. Thompson, M.D.

Boston, Mass., February 21, 1891.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 22, 1891, to February 28, 1891.

Chapin, Alonzo R., Captain and Assistant Surgeon. By direction of the Secretary of War, the leave of absence granted in Special Orders No. 17, January 31, 1891, Department of Dakota, is extended one month. S. O. 41, A. G. O., Washington, D. C., February 20, 1891.

Fryer, Blencome E., Lieutenant-Colonel and Assistant Medical Purveyor. Having been found incapacitated by army retiring boards on account of disability incident to the service, is, by direction of the President, retired from active service this date, under the provisions of Section 1251, Revised Statutes. S. O. 42, par. 15, A. G. O., Washington, D. C., February 24, 1891.

Gardiner, John de B. W., Captain and Assistant Surgeon. Having been found, by army retiring boards, incapacitated for active service on account of disability incident to the service, is, by direction of the President, retired from active service this date, under the provisions of Section 1251, Revised Statutes. S. O. 43, par. 12, A. G. O., Washington, D. C., February 25, 1891.

Shufeldt, Robert W., Captain and Assistant Surgeon. Having been found, by army retiring boards, incapacitated for active service on account of disability incident to the service, is, by direction of the President, retired from active service this date, under the provisions

of Section 1251, revised Statutes. S. O. 43, par. 12, A. G. O., Washington, D. C., February 25, 1891.

De Haune, J. Victor. Captain and Assistant Surgeon. Having been found, by army retiring boards, incapacitated for active service on account of disability incident to the service, is, by direction of the President, retired from active service this date, under the provisions of Section 1251, Revised Statutes. S. O. 44, par. 18, A. G. O., Washington, D. C., February 26, 1891.

Steinmetz, William R., Captain and Assistant Surgeon. Having been found, by army retiring boards, incapacitated for active service on account of disability incident to the service, is, by direction of the President, retired from active service this date, under the provisions of Section 1251, Revised Statutes. S. O. 44, par. 18, A. G. O., Washington, D. C., February 26, 1891.

Owen, William O., Jr., Captain and Assistant Surgeon. By direction of the Secretary of War, is relieved from further duty in the Department of the Missouri, and will report in person to the commanding officer at Jefferson Barracks, Mo., for duty at that station, and by letter to the Superintendent of the Recruiting Service. S. O. 44, par. 2, A. G. O., Washington, D. C., February 26, 1891.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 28, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	6	2
Scarlet fever	147	33
Cerebro-spinal meningitis	2	0
Measles	384	10
Diphtheria	119	40
Small-pox	0	0
Varicella	9	0
Pertussis	4	7
Croup	0	0
Mumps	0	0
Rötheln	0	0

A Sudden Outbreak of Cholera.—Among the outbreaks of cholera which occurred in Burmah last year there was a remarkably sudden visitation at the Moulmein Jail. One evening the prisoners were conducted to their dormitories in the usual manner, without the slightest indication that there was anything wrong. At midnight the seizures commenced, and by six o'clock the following morning nine men had been attacked, and every one of them died. When the day came to a close 31 out of a total of 674 convicts were struck down, and the following day the number of seizures was increased by seventeen, giving for the two days 48 attacks, of which 38 ended fatally. On the third day there were fifteen more seizures, so that in three days ten per cent. of the jail population suffered. Cholera camps were formed outside "the zone of jail influences," but it was some time before the scourge could be shaken off, and by order of the Commissioner 136 convicts were released.—*Indian Medical Gazette.*

Is the Urine of Pregnant Women Poisonous?—Dr. Blanc has injected urine taken from healthy women during the last months of pregnancy into the veins of rabbits, in order to determine the truth of the theory propounded by Rivière, namely, that puerperal eclampsia depended on an autointoxication due to the formation of poisonous matters in greater quantities during pregnancy than in the non-gravid state. The result of thirteen experiments brought the author to adopt the conclusion that a pregnant woman under ordinary conditions of health does not form and does not eliminate more poisonous matters than the non-gravid female. Dr. Blanc has also made experiments to determine the toxic power of the urine in women recently delivered, that is, during the first five days of the puerperium. In this latter condition he found the toxic power of the urine somewhat increased beyond the normal standard but not to any great extent. —*Annales ae Gynécologie.*

Dislocation, and Fractures of the Neck of the Femur—Dr. Keen gives the following tables in the *College and Clinical Record:*

Fracture of Neck.	*Dislocation.*
1. Old persons, as a rule.	1. Adult middle life.
2. In women more frequently.	2. Either sex (men more frequently).
3. Slight force.	3. Severe force.
4. Eversion of toes.	4. Inversion of toes (usually.)
5. Shortening in both.	5. Shortening in both.
6. If you restore to position displacement recurs.	6. If you restore to position displacement does not recur.
7. Usually crepitus.	7. No crepitus.
8. Preternatural mobility.	8. Preternatural immobility.
9. Slight prominence of great trochanter.	9. Great prominence of great trochanter.

He also gave this table as a differential diagnosis between intra- and extra-capsular fracture of the neck of the femur.

Intra-capsular.	*Extra-capsular*
1. Slight injury.	1. Severe injury.
2. Rarely severe contusion.	2. Usually severe contusion.
3. Shortening increases.	3. Remains the same.
4. Crepitus feeble and sometimes absent.	4. Crepitus distinct.
5. Leg nearly (but not entirely) helpless.	5. Entirely so.
6. Shortened radius of rotation.	6. Still more so.
7. Pain tolerably severe.	7. Extremely severe.
8. Usually occurs in persons over fifty years of age.	8. Usually occurring in persons under 50 years of age.
9. More frequently in women.	9. More frequently in man.

Differential Diagnosis of Tumors.—Professor Keen gives this table as of use in making the differential diagnosis of the following varieties of tumors:

Encephaloid.	*Scirrhus.*
1. Soft, elastic, not uniform.	1. Hard and inelastic.
2. Rapid growth, large size, adhesions early.	2. Slow growth, small size, late adhesions.
3. Pain slight and wandering; after ulceration severe and fixed.	3. Pain early, sharp, fixed, and lancinating.
4. Veins enlarged.	4. Veins slightly enlarged.
5. Ulcerations deep, foul, undermined and bleeding.	5. Ulceration deep, edges hard and abrupt.
6. Glands involved early.	6. Glands involved late.
7. Occurs at any age, usually before forty-fifth year.	7. Usually occurs after fortieth year.
8. Occurs most frequently in the breast, testicle, and uterus.	8. Breast, uterus, stomach.
9. Death occurs in from nine to twelve months.	9. Death in from nine to eighteen to thirty-six months.
10. If in breast there is no retraction of nipple.	10. There is retraction of nipple.
11. Family history is bad.	11. Family history is bad.

Sarcoma.	*Adenoma.*
1. May be soft and fluctuating, or hard.	1. Soft and elastic.
2. Growth irregular, adhesions early.	2. Slow growth, no adhesions.
3. Very little pain until ulceration takes place.	3. Pain very slight and neuralgic; menstrual if tumor affects the breast
4. Veins slightly enlarged.	4. Veins normal.
5. Ulceration sooner or later, quite deep.	5. No ulceration.
6. Rarely, if at all, involved.	6. Glands never involved.
7. Occurs in adult middle life, twentieth to fortieth year.	7. Occurs from twentieth to thirtieth year, usually.
8. Connective tissue anywhere.	8. In breast or other glands.
9. Death occurs early or late; simply a matter of time.	9. Never kills.
10. No retraction of the nipple.	10. No retraction of nipple.
11. Family history good.	11. Family history good.

Longevity.—In connection with the pseudo-centenarianism of the Elgin "Methuselah," whose death was recently recorded, the following story will be read with interest: It is well known that people seldom die in Ochiltree. When anyone there gets tired of life, he generally finds it necessary to remove to another parish. Many of the inhabitants, however, do not seem ever to tire of life, and so remain on their native soil till their ages are past all reckoning. Colonel Andrew M'Dowall, when he returned from India, came one day upon an old man sitting weeping on a big stone by the roadside. When he came up, the old man rose and took off his bonnet and wiped his eyes, and said, "Ye're welcome hame again, laird." "Thank you," said the Colonel, adding, after a pause, "I should scarcely know your face; aren't you Nathan McCulloch?" "Ye're richt, 'deed!" said Nathan. "It's just me, laird." "You must be a good age now, Nathan," said the Colonel. "I'm no verra aul' yet, laird," was the reply; "I'm just turn't a hunner." "A hundred!" said the Colonel, musing. "Well, you must be all that. But the idea of a man of a hundred sitting blubbering in that way! What could you get to cry about?" "It was my faither licket me, sir," said Nathan weeping again; "an' he put me oot, so he did!" "Your father!" said the Colonel, astonished. "Is your father alive yet?" "Leevin'? Ay," replied Nathan, "I ken that the day tae my sorrow." "Where is he?" said the Colonel. "What an age he must be! I should like to see him." "Oh, he's up in the barn there," said Nathan, "an' no in a horrid gude humor the noo aither!" They went up to the farm together, and found the father busy threshing the barley with the big flail, and going on at a fearful rate. Seeing Nathan and the laird coming in, he stopped and saluted the Colonel, who, after inquiring how he was, asked him what he had struck Nathan for. "The young rascal," said the father, "there's nae doin' wi' him; he's never oot o' mischief! I had tae lick him this mornin' for cloddin' stanes at his grandfather!" —*Edinburgh Medical Journal.*

Psorosperms in Cancer.—In a paper read before the Havana Society of Clinical Studies by Dr. Albarran on the Micro-organism of Cancer, the author detailed his reasons for believing the bacterial cause of cancer to be a body belonging to the coccidiæ, or, as they are sometimes called, psorosperms, one of the five divisions of the sporozoaria. Some years ago, while examining a cancer of the jaw, he came upon some rounded bodies which were considered by MM. Malassez and Balbiani to be psorosperms analogous to those found in the liver of rabbits. Subsequently they were discovered by M. Darier in a skin disease which is now called "psorospermosis follicularis vegetans," and similar bodies were found in the centre of the nests in epithelioma, especially in those which are in an early stage of development. Both Pfeiffer and Babes have described bodies of similar nature which they have seen in cancers, and subsequently Darier, Wickham, and others demonstrated their existence in Paget's disease and in various forms of cancer. Dr. Albarran himself described at the Berlin Congress a disease of the bladder, consisting of a proliferation of the epithelium, of irregular distribution, giving the inner surface of the organ a papillary instead of a smooth appearance, psorosperms being found in the epithelial urinary casts in their two principal forms—that is to say, rounded bodies and spore-bearing cysts; this peculiar affection he styled "vesicular psorospermosis," and compared it with vesical epithelioma containing psorosperms. Although the cultivation of these bodies has only been very imperfectly carried out, and no inoculation experiments have been made, Dr. Albarran considers that when we follow the change from Paget's disease to true epithelioma, and compare vesical psorospermosis in the human subject and the disease molluscum contagiosum of birds, which is admittedly of psorospermic origin, with epithelioma containing psorosperms, there is a good deal of reason for regarding these organisms as the probable cause of cancer. He goes on to give some directions for finding them, which is not always an easy task, as they do not readily take a distinct stain. If very small portions be hardened in osmic acid and alcohol, and the sections stained with carmine combined with alum or with Ranvier's picro-carmine, the psorosperms will be of a greenish yellow, which is distinguishable from the rose color of the surrounding tissue. A search should be made with a power of 100 to 150 diameters in the epithelial masses for rounded cells, badly stained, larger and more refracting than the rest. These should then be examined with a power of 400 or 500 for the detailed structure—its intra-cellular encysted state, its rounded or elongated form, and the granulations of its protoplasm. Sometimes the membrane of the cyst can be seen to have a double contour, and between it and the retracted protoplasm a clear space can be detected. Sometimes also larger cysts may be seen containing a considerable number of spores in the form of elongated corpuscles. It is needless to say that the author of the paper referred to entirely disputes the claim of Scheuerlen's bacillus to be the cause of cancer. —*The Lancet.*

Dr. Holmes on Specialism.—Oliver Wendell Holmes puts in the mouth of a young doctor the following words: "I am very glad," he said, "that we have a number of practitioners among us who confine themselves to the care of single organs and their functions. I want to be able to consult an oculist who has done nothing but attend to eyes long enough to know all that is known about their diseases and their treatment—skilful enough to be trusted with the manipulation of that delicate and most precious organ. I want an aurist who knows all about the ear, and what can be done for its disorders. The maladies of the larynx are very ticklish things to handle, and nobody should be trusted to go behind the epiglottis who has not the *tactus eruditus*. And so of other particular classes of complaints. A great city must have a limited number of experts, each a final authority to be appealed to in cases where the family physician finds himself in doubt. There are operations which no surgeon should be willing to undertake unless he has paid a particular, if not an exclusive attention to the cases demanding such operations. All this I willingly grant; but it must not be supposed that we can return to the methods of the old Egyptians, who, if my memory serves me correctly, had a special physician for every part of the body; in short, falling into certain errors, and incurring certain liabilities. The specialist is much like other people engaged in a lucrative business. He is apt to magnify his calling, and to make much of any symptom which will bring a patient within range of his battery of remedies. I found a case in one of our medical journals a couple of years ago, which illustrates what I mean. Dr. ——, of Philadelphia, had a female patient with a crooked nose—deviated septum, if our young scholars like that better. She was suffering from what the doctors call reflex headache. She had been to an oculist, who found that the trouble was her eyes. She went from him to a gynecologist, who considered her headache was owing to causes for which his specialty had remedies. How many more specialists would have appropriated her if she had gone the rounds of them all I dare not guess; but you remember the siege in which each artisan proposed means of defence, which he himself was ready to furnish. Then a shoemaker said, 'Hang your walls with new boots!' Human nature is the same with the medical specialist as it was with ancient cordwainers, and it is, too, possible that a hungry practitioner may be warped by his interest in fastening on a patient, who, as he persuades himself, comes under his medical jurisdiction. The specialist has but one fang with which to seize and hold his prey; but that fang is a fearfully long and sharp canine. Being confined to a narrow field of observation and practice, he is apt to give much of his time

to curious study, which may be *magnifique*, but it is not exactly *la guerre* against the patient's malady. He divides and subdivides, and gets many varieties of diseases, in most respects similar. These he quips with new names, and thus we have those terrific nomenclatures which are enough to frighten the medical student, to say nothing of the sufferers staggering under this long catalogue of local infirmities. The 'old fogie' doctor who knows the family tendencies of his patient, who understands his constitution, will often treat him better than the famous specialist who sees him for the first time, and has to guess at many things. The old doctor knows from his previous experience with the same patient and the family to which he belongs. It is a great luxury to practise as a specialist in almost any class of diseases. The special practitioner has his own hours, hardly needs a night-bell, can have his residence out of the town in which he exercises his calling, in short lives like a gentleman, while the hard-working general practitioner submits to a servitude more exacting than that of the man who is employed in his stable or kitchen. That is the kind of life I have made my mind up to."

Pure Water.—In the "Proceedings of the Florida Medical Association" Dr. Porter says that he once heard a composition on water in which the writer said: "Water is a substance used for washing and to sail ships in, and some people drink it." It is only when people will drink water that is impure that an objection can be raised as to the use of too much of it, and water as a temperance beverage, from a medical stand-point, is then brought into disrepute. Artesian well water and rain-water, properly filtered, are the only safe drinking-waters; and the drinking of ordinary well water, which is so general in this State, is a practice that cannot be too strongly condemned. The wells, for the most part, are shallow excavations, or are driven into the ground only a short distance and collect by seepage and too frequently the drainage from the dwellings and barnyards. The fact that water from these wells is free from color and odor argues nothing in favor of its healthfulness or harmlessness for human consumption, as very often such water upon analysis shows a large percentage of organic impurities and albuminoid ammonia in such quantity as to imperil the health of those using it. It is a difficult matter to persuade the people that in drinking well-water they are, in a large majority of instances, poisoning their systems and inviting a long and tedious illness from typhoid fever which may result in years of shattered health and perhaps death. You will oftentimes be met with the argument that this or that particular well has been used by the family for a long period of years with no apparent detriment to them, and no better water could be found in the neighborhood. To the query as to the prevalence of fever or intestinal disorders, the answer will be: "Oh! yes; we have fevers such as are usual about here, but we always have had them at certain seasons of the year." Now, it is the experience of many writers on this subject, that it is at certain seasons of the year—either at the dry season when the water is very low, or during the wet weather when the wells are filled to the curb—that the "continued fevers," as they are now called, generally prevail. If the people in the small towns and rural districts of the State will drink well-water, they should be advised to boil it thoroughly and aërate and filter it before using.

A Proposed Colony for Epileptics.—The following is the text of a bill introduced before the Legislature of the State of New York on January 29th: An Act providing for the appointment of commissioners to establish a colony for epileptics in the State of New York. The people of the State of New York, represented in Senate and Assembly, do enact as follows:

Section 1. Three persons, two of whom are residents of New York County, possessing expert knowledge of the needs of epileptics and the epileptic insane, and one of whom is a resident of Westchester County, shall be appointed by the Governor within ten days after the passage of this act, and shall constitute a commission to determine upon the manner of providing for the education, employment, care, and treatment of all the epileptics and epileptic insane of this State, including those now congregated in the almshouses and insane asylums upon public charge, and also those not under State or county care. Said commission is authorized to select a site in Westchester County, as near as convenient to New York City, to consist of not more than three hundred acres of farming and wood land; to adopt plans which shall furnish provision on the cottage or pavilion system ultimately for from one thousand to two thousand epileptics, such plans to include methods of heating, lighting, sewerage, water-supply, and prevention of danger from fire, and, in addition to accommodations for dwelling purposes, to include school-rooms, workshops, a hospital, a pathological laboratory, and outbuildings for agricultural, floricultural, horticultural, and dairy purposes.

Said commission shall provide the land needed by purchase or otherwise.

Sec. 2. The members of said commission, before entering upon the duties of their office, shall take and subscribe an oath or affirmation, before some competent authority, faithfully to discharge all the duties required of them by this act. They shall each be entitled to receive the necessary expenses incurred while discharging the duties assigned them.

Sec. 3. When said commission shall have selected a site and complied in all respects with the provisions of section one of this act, a report thereof shall be made in writing by said commission to the Governor, who shall thereupon appoint seven managers, who shall approve of the plans and let the contract, and have charge of the erection of the buildings, as provided by law. Said managers shall be appointed and confirmed according to the laws governing the appointment of managers of other benevolent institutions of this State; provided, that the said commissioners and managers shall not enter into any contract for the erection of said buildings until the money has been appropriated by the Legislature to pay for the same.

Sec. 4. That there be and is hereby appropriated out of any money in the treasury to the credit of the general revenue fund, not otherwise appropriated, the sum of ten thousand dollars for the expense of said commission, and for the purpose of complying with the provisions of section one of this act.

The accounts of expenditure, including the expenses of the commission, shall be audited and allowed by the Comptroller of the State.

Sec. 5. This act shall take effect immediately.

THE OPERATIVE SURGICAL TREATMENT FOR ANEURISM OF THE FIRST TWO PORTIONS OF THE SUBCLAVIAN.[1]

By JOSEPH D. BRYANT, M.D.,

NEW YORK.

YOUR Chairman addressed me, not long since, a somewhat urgent request, tinged with a coloring of entreaty, asking if I would contribute to this meeting of the Section a paper on the subject of which, I fancy, he hoped a profitable discussion might make amends for the various brevities of the exciting cause of the debate.

The subject of discussion selected, "The Operative Surgical Treatment for Aneurism of the First Two Portions of the Subclavian," is not at all new in the idea, though perhaps differently expressed than before. I desire to say at this time that you will not be plagued by the announcement of the employment of any strange expedient of treatment of my own, nor, in fact, of a startling or unusual result of treatment. The suggestive stimulus of a recent case of mine that was thought to bear on the title of this paper, is offered in part as the reason for it, and the history of the case will be employed as a text from which it is hoped useful conclusions may be drawn.

Mary D——, possessed of average intelligence, aged fifty-five, was admitted to Bellevue Hospital August 16, 1890. On admission an examination showed the existence of an aneurismal tumor, extending about one inch and a half above the right clavicle, behind and nearer to the outer side of the sterno-cleido-mastoid muscle. From this situation it extended obliquely downward to the episternal notch, thence behind the sternum, although not pressing against it. Percussion at and around the immediate neighborhood of the right sterno clavicular articulation disclosed a marked degree of dulness. The personal and family histories of the patient contained nothing suggestive, except perhaps a prolonged attack of acute articular rheumatism, from which she had recovered a year or so before admission. No specific history. She complained of constant pain, fulness, and throbbing, which had existed with varying intensity for several weeks before admission, at the seat of the tumor. The fingers could not be pressed between the tumor and the clavicle, or the sternum, on account of the size of the growth. Huskiness of the voice was marked, and had continued with varying degrees of severity, without the presence of the usual assignable causes of it, for some time prior to admission. The tumor was first noticed ten weeks before admission, at which time it was about one-half as large as on entrance to the hospital. Occasional attacks of nausea, dizziness, and headache, with ringing in the ears, and flashes of light, followed from the time of the discovery of the tumor up to the present date. No evidence of organic disease was discovered. The pulsation of the radial artery of the right was appreciably weaker than that of the left side. A soft bruit, but no thrill, was present. A somewhat indefinite history of previous slight laryngeal spasm was elicited. No difficulty in deglutition or respiration had occurred, due to direct pressure.

The patient was placed in bed and put on a low diet, combined with iodide of potassium in large doses. At the end of the first month the tumor appeared to be smaller, certainly it had not increased in size. At this time it was examined by Dr. E. G. Janeway and Dr. A. A. Smith, with the view of confirming the suspected site. The first portion of the subclavian, with probable involvement of the innominate, was deemed to be a discreet and rational diagnosis in this respect. The treatment was continued, with ever-varying belief as to whether or not the tumor were larger or smaller, harder or softer, than on a previous occasion. The element of doubt in these cases frequently staggers belief; and it seems not improbable that the author of the sentiment, "Who never doubted, never half believed," was a consulting physician in such matters, and coined the sentiment for selfish and politic purposes only.

On November 14th the patient had a sudden and severe attack of dyspnœa, attended with nausea, vomiting, ringing in the ears, flashes of light, and great cyanosis. Just subsequent to this attack she was examined by Dr. Stephen Smith and Dr. Dennis, who concurred in the diagnosis already made. Three other attacks of a similar nature, though less severe, happened during the next month. These attacks were apparently mitigated by the use of chloroform and nitrite of amyl. No appreciable changes in the size or shape of the tumor attended these obstruction manifestations. As the result of the preceding consultations it was decided to tie the common carotid and subclavian arteries, either simultaneously or with an interval, as might seem proper after ligature of the carotid. On December 20th the common carotid was tied, immediately above the omo hyoid, at a clinic given in the Bellevue Hospital amphitheatre. Slight loss of power of the right side of the face, unnatural dilatation of the right pupil, and dizziness were the only important cerebral manifestations of circulatory interference that followed the ligaturing, and all of these disappeared within the first week after the operation. During the first week it was noted: 1, That all evidences of the previous long-continued hoarseness had disappeared; 2, that the patient's sensations of pain, fulness, and throbbing at the seat of the tumor were no longer complained of; 3, that the tumor appeared to be smaller and firmer.

Toward the end of the second week the tumor was again examined by Dr. Stephen Smith, who unhesitatingly expressed the opinion that it was much reduced in size and increased in density. Twenty days after the ligature of the carotid the tumor had disappeared almost entirely from behind the posterior border of the sterno cleido-mastoid, and, without extending higher, had advanced toward the median line of the neck, entering further into the inferior carotid triangle. However, the tumor appeared smaller, and the dulness first noticed at and about the sterno-clavicular articulation was much diminished in area and lessened in intensity.

On January 17th (four weeks after ligature of the carotid) the subclavian artery was ligatured at the third portion. Nothing unusual followed as the immediate result of this operation. This vessel, like the carotid, was tied with an ordinary good-sized catgut ligature. Both wounds healed throughout, by first intention, at once. One week after the last operation the patient expressed herself as comfortable in all respects. On the eleventh day, however, while the tumor was being examined, the patient complained suddenly of a severe pain in the right side of the head, which was followed quickly by nausea, vomiting,

[1] Read before the Surgical Section of the New York Academy of Medicine, February 19, 1891.

and well-marked ptosis of the right eye, together with right myosis. The day following, the pain and vomiting continued, the stomach rejecting all alimentation. The respirations became hurried, attended with small, moist râles in the right lung. On the thirteenth day the patient died. The result of the autopsy in all of the details is well expressed in the following statement of Dr. Hermann Biggs, who made it:

"The heart seemed of about normal size and showed only moderate sclerotic and fatty degeneration in the myocardium. The mitral valves were nearly normal, and the aortic valves, though slightly thickened, were perfectly competent. The aorta was the seat of very extensive chronic deforming endarteritis as shown by numerous patches of atheroma, atheromatous ulceration, sclerosis, calcification, etc. This process was more marked in the thoracic and abdominal aorta than in the arch of the aorta, and extended from the aorta into the smaller vessels to a moderate degree. There was a dilatation of the ascending and transverse portion of the aortic arch along its external convex surface. Some idea of the amount of this dilatation may be gained from the transverse measurement of the vessel. After opening the aorta the transverse measurement of the aortic lumen, just above the valves, was 3½ inches. One inch and a half higher up it was 4½ inches, and at the origin of the innominate artery 4 inches. The innominate itself was also considerably dilated, especially near its origin, where its circumference was one half inch greater than just below the bifurcation. There was a firm thrombus in the right common carotid, situated one and one-fourth inch from its origin. Surrounding the third portion of the right subclavian artery was a heavy catgut ligature, and on either side of this was a firm thrombus. In the right vertebral artery, one-half inch from its termination in the basilar, was a thrombus (which seemed to have formed around an embolus) which completely obstructed the vessel. Beginning in the lower part of the floor of the fourth ventricle, on the right side, was an area of softening that extended upward nearly through the pons. In the right hemisphere of the cerebellum, also, was a large area of softening, which involved nearly the whole of the centre of the hemisphere. The arteries of the circle of Willis and their branches presented the lesions of an advanced endarteritis. Fibrinous deposit had not taken place within the aneurism at any portion of its surface."

There are some facts in connection with these findings that appear to deserve special attention at this time.

1. The actual location of the aneurismal changes, as compared with their supposed site.

The presence of the tumor above the clavicle, and behind the sterno cleido-mastoid, pointed to disease of the subclavian, which, when taken in connection with the hoarseness and laryngeal obstruction symptoms, and the dulness at and about the right sterno-clavicular articulation, seemed at that time to make the localization element of the diagnosis almost certain. The sequel, however, only serves to emphasize the fact already enunciated, that a correct diagnosis of the location of aneurismal tumors at the root of the neck is an impossibility, except in special cases.

2. The absence of stratified or other thrombi within the sac of the aneurism.

The well marked diminution of the size of the tumor and the increase of its density, which followed ligature of the vessels, were thought to have been due to fibrinous deposit. These changes encouraged the belief on the part of all those who examined the growth that a definite curative process, due to fibrinous deposit, was taking place. However, such appears not to have been the case. And in this connection I will mention a most striking fact that was noticed, after ligature of the carotid, by those to whose attention it was called. Immediately after the ligature of this vessel the circulation of the right subclavian was arrested at the third portion by pressure of the thumb, with the view to determine its effect on the size and tension of the aneurism. Certainly this act did not, so far as I could discover, cause the least increase in the size and tension of the growth; in fact it seemed to me as if the size were diminished by the manipulation. Being unwilling to rely on my own sense of touch in this matter, I asked Dr. Banks, the house surgeon, to make the test, and did so without speaking of the impression it had made upon me. After repeated trials Dr. Banks asserted positively that the aneurism was lessened in size by the arrest of the circulation in the subclavian. This did not satisfy me. I then requested Dr. Banks to command the subclavian, while my own fingers were applied to the growth with my back turned to the patient. With these precautions I would have no means of knowing whether the circulation were arrested or not by the doctor's manipulations. I then endeavored to tell, by the impressions conveyed to my fingers by the growth, whether or not the circulation were arrested in the subclavian, basing my belief, of course, on the appreciation of the varying size of the tumor as modified by the pressure manipulations. To my astonishment, and to the amusement of those present, my predictions were amiss, for when I declared the tumor the smaller, the circulation was arrested; when the larger, it was uninterrupted. Some days after this time I asked Dr. Stephen Smith to make the test and express his opinion of the matter. After a careful trial Dr. Smith was unable to note an appreciable change in the size of the aneurism, due to interruption of the subclavian circulation. If the initial observations were true, then surely a lessening in the size of aneurisms may happen when similarly circumstanced, even though no fibrinous deposit ensue. Whether or not these impressions were genuine or delusive can be determined only by a more careful study of subsequent cases.

3. The fatal thrombus of the vertebral artery.

The brain-softening following the plugging of the vertebral was the immediate cause of death, consequently brief attention to this phase of the case is important as bearing on the ligature of this vessel in the course of treatment of aneurisms amenable to it. At one time I had entertained the self-proposition in this case to tie the vertebral at its association with the atlas, after allowing sufficient time to elapse to have gained all that might arise from the collateral relations of its cervical branches with important contiguous vessels. This case demonstrates the result that would have followed had the proposition been deferred six weeks after ligature of the common carotid. The proposal to tie this vessel, after a longer or shorter period following ligature of the innominate and common carotid simultaneously, is made especially significant in old people by the result of this case. However, the dangers attending the Charybdic shoals of supplementary measures in aid of innominate ligature are not less momentous than the inevitable Scylla-like results of the cases demanding it.

4. The gradual forward change in the position of the supra-clavicular portion of the aneurism, which followed soon after ligature of the common carotid, is in no way explained by the post-mortem examination.

In selecting the title of the paper I was actuated also by a desire to have considered at this time the better plan of procedure in aneurismal growths so situated as to admit of either of two procedures, viz., ligature of the innominate artery, or distal ligature of the common carotid and subclavian arteries, either simultaneously or consecutively. The importance of such a decision is obvious, more especially if it shall appear that the latter proposition affords an equal relief from suffering with an equal saving of life, since its performance can be easily accomplished by anyone having an ordinary well-founded surgical attainment. It is fair, too, in this connection, to add to either of these procedures other expedients that may be thought to exercise an equal influence in contributing to the necessities of both. The further consideration of the subject will be continued under the following titles: 1. What is the lease of life

of those afflicted with aneurism of the first two portions of the subclavian when treated by measures that may be employed by physicians and surgeons alike? 2. What is the lease of life when treated with distal ligature of the subclavian and carotid (*a*) when simultaneously applied; (*b*) when applied consecutively? 3. What is the lease of life with ligature of the innominate? 4. What operative expedients may be employed, that can be thought to exercise an equal influence in contributing to cure, with either the distal or proximal methods of ligaturing? 5. Conclusions.

It is, indeed, practically impossible to find reports of a sufficient number of undoubted cases of aneurism of the first two portions of the subclavian, together with innominate involvement even, from which to make a reliable statement as to the results of distal and proximal ligature, when compared with "no treatment," and with treatment employed by physicians alone in such cases. Therefore it is deemed wiser to inquire as to the lease of life in cases of subclavian aneurism, when treated by precautionary, medicinal, and manipulative methods only, all of which a physician may readily employ.

It is assumed that no patient has yet died of aneurism who had not been subjected to some variety of treatment; provided, of course, that the case had fallen under the timely scrutiny of medical observation. Precautionary treatment may be said to include regulation in dietetic and physical matters, in fact it is often, though improperly, denominated as "no treatment." Mr. Poland's 22 cases with Mr. Barwell's 9 cases, in all of which rest and regulated diet comprised the means employed as treatment, may with propriety be presented as reasonably answering the question, at this time, as to lease of life without operative interference. Two of these 31 cases recovered slowly, presumptively as the result of treatment; 2 recovered quickly, probably as the result of incidental fixation of a clot; the remaining 27 died, or at least received no benefit. According to these figures it appears that about thirteen per cent. of the cases recovered, one-half of which were cured by the treatment itself. Strict regimen, with rest and occasional venesection, are credited with 1 direct and 2 coincidental cures in 13 cases. The methods by proximal compression, direct compression, and also by parenchymatous injections of ergotin, have not been employed singly in a sufficient number of cases to warrant their precedence of the other methods just mentioned. However, they may with propriety be classed as medicinal and manipulative measures, calculated to aid the milder ones in the establishment of a cure. It now appears that of the 44 cases that were treated by medical methods, 7, or about sixteen per cent., were cured; 3 of which were direct and 4 coincidental cures. If to this result be now added those obtained by direct pressure and the ergotin injections, we have a total of 50 cases, of which 9, or eighteen per cent., were cured, 5 of which were direct cures and 4 coincidental ones. The reports of distal ligature of the subclavian and carotid arteries, either singly, simultaneously, or consecutively performed for aneurism at the root of the neck, and for subclavian aneurism, do not furnish a sufficient number of isolated cases of distal ligature for aneurism of the first two portions of the subclavian, or of the entire vessel, to enable one to judge of its worth in this respect from recorded experience.

Of 40 cases thus far examined from the original reports, at my request, by Dr. Glover C. Arnold, in which distal ligature had been employed for aneurism at the root of the neck, but one or two can be crowded even into the category of aneurism of the first two portions of the subclavian. It is not because this variety of aneurism does not occur, but because of the uncertainty of diagnosis they are relegated to the broader and self-evident site — the root of the neck. As to distal ligature for aneurism at the root of the neck, nothing remains to be said after the admirable paper on this line of thought recently read before the Surgical Society by Professor T. M. Markoe. In this paper Professor Markoe recorded 74 cases. To these can now be added the one of my own, which was the predisposing cause, at least, of this paper.

Little favorable can be said of the lease of life with ligature of the innominate. No household word is more familiar than is the result of this operation to the medical profession. This vessel has been ligatured twenty-four times at least. Fifteen of these cases survived the operation an average of nearly nineteen days each, the longest period being sixty seven days, the shortest twelve hours. The great majority died of secondary hemorrhage that happened at or about the time of the coming away of the ligature. A few succumbed very soon after the operation from complications directly incident to its performance. The well-known case of Smyth, of New Orleans, survived the operation, narrowly escaped the usually fatal result, lived ten years, then died from rupture of the re-formed aneurism, the result of reverse collateral circulation. Among the recent cases may be mentioned Thomson's (1882), which died of hemorrhage on the forty-second day; Banks's (1883), which died from the same cause at the end of the thirty-seventh day; also Bull's (1884), which died on the thirty-third day from hemorrhage. The later cases possess unusual significance, since they were performed not only by representative surgeons, but also with the aid of the highest known art of antiseptic technique. Surely the fatal termination has been much longer deferred by modern methods, but still, secondary hemorrhage claims its own with an assurance that as yet admits of no rebuff. The improvements in the physical characteristics of the ligature, and in the methods of its application are now quite sufficient to justify the operation, provided it be possible to obviate the pernicious influences arising from the contiguous and persistent blood-current distal to the ligature and those resulting from diseased arterial walls. It is of special interest in this connection to notice the condition, respectively, of the innominate, subclavian, carotid, and vertebral arteries, and the sac, as found after death from ligature, in the very few cases thus fully reported.

Bland's case (1832) died of hemorrhage on the eighteenth day. The innominate and carotid were closed by solid clots; the subclavian open; the vertebral and sac not mentioned. Bickersteth's case (1868) died of hemorrhage on the sixth day. A firm clot was in the innominate at the cardiac side of the ligature; subclavian occluded; carotid open and the seat of hemorrhage; vertebral and sac not mentioned. Thomson's case (1882), ox-aorta ligature, died of hemorrhage on the forty-second day; innominate, subclavian, and axillary arteries firmly closed; carotid closed by a clot with a soft centre; all branches of the first portion of the subclavian were pervious. The sac was lined with fibrinous layers to the depth of one-third of an inch, and newer layers appeared to be forming. In Bull's case (1884) the right common carotid and the right vertebral arteries were ligatured simultaneously with the innominate, with a double catgut ligature. This patient died of hemorrhage from the cardiac side of the innominate ligature on the thirty-third day. The innominate stump was closed with a soft clot, which was continuous with one in the aorta. The calibre of the innominate stump was twice the usual size, the walls were thickened and contained patches of fatty degeneration. The carotid was closed by a firm clot for three inches; the clot of the vertebral was not firm and the end of this vessel was imbedded in a mass of granulations. The aneurismal sac embraced the second and third portions of the subclavian was about the size of a duck egg, and contained bloody pus and disintegrating clots. In only one other case noted, Gore's (1856) is mention made of the contents of the sac, and this, in the following language: "The sac was contracted and filled with coagulum." This case had died on the seventeenth day from hemorrhage. But one rational inference can be drawn from the failure to mention the existence or non-

existence of recently formed fibrinous stratifications in the aneurismal sacs of other cases; if looked for, they were not present, for surely if they had been, their presence would have been hailed with delight, and heralded as glad tidings of surgical joy. The fatal hemorrhage in Thomson's case took place from an ulcerated opening at the point of bifurcation of the innominate, which involved the anterior portions of the walls of those vessels. If we again turn our attention to the successful case of Smyth (1864), the reasons for this success will become more apparent in view of the site of the fibrinous clots in the fatal cases just quoted, and the situation of the ligatures that caused their formation.

Smyth ligatured the innominate a quarter of an inch below the point of bifurcation, also, at the same time, the carotid an inch above its point of origin. On the fifteenth day hemorrhage took place, but was controlled by direct pressure. Hemorrhage occurred again on the thirty-third and fifty-first days, and the vertebral artery was tied on the fifty-fourth day. Following this the patient recovered, and lived for ten years, as before stated. The success in this case appears to have been due only to the control of the blood current in the subclavian, as obtained by the consecutive ligaturing of the carotid, and later, the vertebral artery. If a repetition of these expedients were to secure a similar result, with measurable certainty, then indeed they are more justifiable to-day than in 1864, since the technique of to-day will contribute in not a small degree to a favorable issue.

The operative expedients that may be employed, that can exercise rational and reasonably safe influence in contributing to cure in either the distal or proximal methods of ligature, are few, indeed, and cannot as yet be given an undisputed prominence. I shall speak of but two at length, viz., galvano-puncture and the recent method advanced by Macewen. Barwell reports three cases treated by the former method, one of which was cured, the remainder not benefited. Ciniselli collected 50 cases of aneurism treated by this method, of which 23 were successful, 20 failed, and 7 died; surely forty-six per cent. of recoveries by one means alone is a most satisfactory accomplishment. It is fair to say, however, that no mention is made of the size, location, and other important characteristics of these aneurisms, in the report consulted by me. It is likewise proper to add that the after-treatment in these cases, viz., pressure, rest, ice, etc., may have contributed to the cure quite as much as the method itself. However this may be, the results are extremely satisfactory, and the treatment is worthy of repetition. The introduction of metallic substances into the sac offers but little hope of cure; but whether or not the employment of the electric current at the same time will not prove acceptable remains to be determined. The method of Macewen, as set forth by himself in his recent address on aneurism, published in the *British Medical Journal*, November 15 and 22, 1890, together with the results obtained in the four cases operated on by him, is deserving of special attention, inasmuch as this expedient can be employed with possibly equal advantage in connection with both the distal and proximal ligaturing of subclavian aneurism. At all events the good claimed for it can be properly sought for after distal ligature of the subclavian and carotid arteries. The aim is to cure by the induction of the formation of white laminated thrombi within the sac. In other words, to endeavor to stimulate the efforts of nature in the production of the consecutive layers of fibrin that characterize nature's cure. For this purpose he employs a strong, round pin of sufficient length to traverse the dimensions of the aneurism. The diameter of this pin is proportionate to the thickness of the tissue through which it is to be passed while entering the aneurismal sac, always remembering that the smallest size consistent with the necessary penetrating power should be employed. It is pushed into the aneurism and carried to the opposite surface of the sac, and no further. The end is then caused to irritate this surface by manipulations of the operator or by movements caused by the blood-current—by the former agency if the penetrated wall be thick, by the latter if it be thin. Ten minutes' application at one point appears to be quite sufficient for the purpose; then the direction may be changed again and again, and the process repeated until, in fact, the entire opposite internal surface has been acted upon. As yet I have not had personal knowledge of the employment of this measure, but certainly I should have no hesitation in using a method bearing the approval of so able a teacher as Macewen, especially when emphasized by the results he has thus far secured by its use.

The first case was one of advanced thoracic aneurism. It had flattened the trachea by pressure and threatened life from dyspnœa. The pins were employed in the manner just described, at a few days' interval, on several occasions being retained frequently in the sac for twenty-four hours—at one time for forty-eight hours. Considerable consolidation followed, but the patient died from dyspnœa at the end of one month. At the autopsy it was found that two-thirds of the interior of the aneurism was filled with a firm, white, laminated thrombus. It was thickest at the portion to which the pin-point had been applied; thinner at the portion where the pins had entered; thinnest at the portion unirritated.

The second case was an aneurism of the upper part of the right femoral, involving the external iliac, which measured five inches in diameter. Pressure was applied to the common iliac until pulsation in the sac had entirely ceased. Then a long steel pin was passed in the manner before described to twelve different parts of the sac, with intervals of ten minutes each. The pin was then removed entirely, and pressure over the single puncture was made for about five minutes. Within two hours the walls were firmer, and at the end of two months the aneurism was entirely cured.

The third case was one of the upper part of the abdominal aorta measuring about three inches in circumference. The pin irritation was applied to this case on three separate occasions. At the end of a month the tumor could be determined only with great difficulty, and then seemed to be like a hard mass raised by the aortic pulsations. The patient, an engine-driver, returned to his labor, and two and a half years later seemed to be in good health.

The fourth case was an intra-thoracic aneurism of the subclavian, attended with great pain, numbness, œdema, and loss of power in the left arm. The sac was four inches in depth, and three in width. In this case the pin was permitted to remain nine hours in the sac, although frequently changed at the point so as to irritate the surface thoroughly. This measure was repeated four times in all, with an interval of seven to fourteen days. As the result of these sittings, and of several subsequent ones, the treatment was discontinued, owing to the great thickness of the sac walls preventing the introduction of the pin. Eight months after the first treatment the patient was in good health and free from pressure symptoms. If these successes can be duplicated in similar cases, then, indeed, a new and valuable expedient of treatment has been presented for the relief of the unfortunate.

Conclusions.—1. The lease of life gained by the so-called medical treatment of subclavian aneurism emphatically teaches that its employment should precede all other methods.

2. The lease of life following distal ligature of the subclavian and carotid arteries, for the cure of aneurism of the first two portions of the subclavian, cannot as yet be estimated, because of the paucity of these cases that have an undoubted diagnosis.

3. The lease of life following ligature of the innominate alone, for subclavian aneurism, does not justify the operation; but ligature of the innominate, when supplemented with simultaneous and consecutive ligature of the associated contiguous arteries, or by other expedients

equally well intended to aid the cure. is worthy of favorable consideration.

4. The lease of life gained by the pin-irritation method of Macewen, and galvano-puncture with its associated treatment, warrants a strong belief in the special benefits of these expedients when employed singly or with ligaturing.

VESICAL HEMORRHAGE IN PREGNANCY, WITH REPORT OF A CASE.[1]

By MARGARET A. CLEAVES, M.D.,

NEW YORK.

"VESICAL hemorrhage during pregnancy is not exceedingly rare, though so regarded," says Dr. Alexander J. C. Skene.[2]

Byford, Coulson, and Keyes make no mention whatever of this condition during pregnancy, but all speak of it as of not infrequent occurrence and good prognosis in the unimpregnated state.

In answer to inquiries circulated among a number of physicians[3] one case was reported, in which there were no symptoms, nothing to cause alarm, save the presence of a large amount of blood in the urine, which naturally frightened the patient. She was delivered at term of a dead child after a dry labor. There was little or no liquor amnii, and the death of the child, as well as the hemorrhage, were attributed by the doctor to its absence.

Etiology.—Dr. Skene[4] says, "All the cases that I have seen during pregnancy have been due to acute congestion and from distended vessels which give rise to a condition like varicose veins, and called by some hæmorrhoids of the bladder, and lastly by ulceration caused by cystitis."

"Varicose veins of the bladder found in pregnant women, usually not primiparæ, are caused by interruption of venous circulation, induced by pressure of gravid uterus."[5]

Regardless of pregnancy "cystorrhagia is usually due to some important disease of the bladder, a symptom rather than a disease."[6]

"Hemorrhages may occur in purpura, typhus, and typhoid fevers, in villous cancer, lesions of structure, and from obstructed portal circulation. The most marked predisposing cause in women is the hemorrhagic diathesis."[7]

According to Byford[8] "Hemorrhage from the bladder, not the result of organic lesions of that organ, is not in frequent. It occurs about the time of the menstrual flow and is rarely if ever sufficient to cause alarm."

"Vesical hemorrhage," according to Keyes,[9] "occurs after injuries, scurvy, hemorrhagic and eruptive diseases, cystitis, strangury from cantharides, ulceration of neck, as in tubercular or cancerous cystitis, and as a vicarious menstruation."

"Severe hemorrhages are especially liable to occur," says Winckel,[10] "when there are varicosities of the vesical neck, what may be called vesical hæmorrhoids. They are especially liable to occur in pregnant multiparæ. Simple hemorrhages are of good prognosis."

Further, according to Winckel, "Among the two thousand five hundred post-mortem examinations of female subjects at Dresden City Hospital, made by the prosector, hyperæmia alone was found but four times, while ecchymoses and hemorrhages were found twenty-one times."

"The presence of blood in the urine is an early symptom of stone. Hæmaturia[11] is a marked symptom of some form of vesical tumor. It occurs in varix of the bladder, in tropical countries from a vesical parasite, and may be caused by and be a symptom of tubercular, croupous, and diphtheritic forms of inflammation." In a research which included an examination of the Surgeon-General's library at Washington, the following is the only case which I have been able to find. Doubtless there are many others, but so incorporated in current literature as to be difficult of access.

CASE.—*Cystitis with Bloody Flux, Simulating Hemorrhage from the Uterus.*[1]—"A woman, six months pregnant, came to the clinic, complaining of loss of blood whenever she urinated; she complained at the same time of pains in lower abdomen and sensation of weight about the genitals. She could, moreover, feel the movements of the fœtus. M. Dubois examined the woman, and found nothing abnormal about the cervix; the finger, after exploring that region, came away unstained with blood. But on introducing a sound catheter into the bladder, severe pains were felt about the urethra. A small quantity of blood-stained urine escaped, and when the sound was withdrawn its extremity was stained with a bloody matter. This hemorrhage, which was first looked upon as coming from the uterus, was found to be symptomatic of a vesical inflammation."

The case which I am now about to report, and which occurred in my private practice, is not introduced on account of the treatment instituted, but on account of its etiology and the seeming rarity of similar cases.

On October 17, 1888, there came under my observation Miss C——, aged twenty; single; eldest of three children, two girls and one boy, all of whom were living. Father living and well. Mother died of consumption. Patient a typical blonde. She entered my office on the above date bearing upon her countenance the most unmistakable evidences of extreme suffering. I was convinced of her pregnancy the moment I saw her, and suspected that she came for advice with the idea of getting out of her trouble in some other than the legitimate way.

In answer to my inquiries she stated that she had always been well, at least so considered herself. There were present no evidences of tubercular trouble. Menstruation, however, had never been regular, varying in frequency from two to eight weeks. Flow always scant; never had pain nor discomfort during the menstrual cycle. Always had some leucorrhœa afterward. This became continuous during fall and winter of 1887, and still further increased in quantity during the summer of 1888, which she attributed to being on her feet a good deal. She distinctly remembers that she had just completed a period, February 24, 1888, and thinks she had one in March. She further stated that she had been perfectly well, had had no nausea, no trouble in any way save from constipation. That on October 2d she noticed a stain on her clothing and supposed she was menstruating. For three days had a little discharge, but no pain nor discomfort. This discharge, she said, came from the vagina. On the night of October 5th she stayed up to care for her brother, who was ill. Thought she took cold. On October 6th commenced to have a continuous flow of urine and blood, accompanied with intense pain in the lower abdomen. About every fifteen minutes had a gush of blood and clots. This state of things lasted for three days. At the end of that time blood continued to pass with the urine, but not alone nor in clots as before. Incontinence persisted, there being no cessation whatever to the constant passage of bloody urine. The patient found it impossible to assume the recumbent position on account of the extreme pain from which she suffered across the lower part of the abdomen whenever attempting it. From October 9th, up to the date of her visit (October 17th) she had been obliged to sit or stand both night and day. After the cessation of the hemorrhage, and about October 10th, she began to have fever every day, and at times to be chilly. Before and during the active hemorrhage had no chills nor fever. Suffered in

tense pain all the time and had not slept since the night of October 8th.

In compliance with my request she loosened all her clothing, removed her corset, and placed herself in the ordinary dorsal position upon the examining-chair. The latter she did with the greatest difficulty, betraying by her movements and facial expression evidences of the most intense pain, which she located over the lower part of the abdomen, and especially over the bladder. When I placed my hand upon the abdomen I could distinctly feel the movements of the fœtus *in utero*, and upon auscultation heard the fœtal heart-sounds very clearly.

Upon instituting a vaginal examination I found her clothing, undergarments, skirts, everything to her dress, stiff and stained with bloody urine; while both from her person and clothing there was exhaled the most intense and disagreeable ammoniacal odor. She said that she changed her clothing repeatedly during the day, but that she had been able to keep nothing clean nor dry for over a week. The external genitals, with the nates, were red and excoriated, and altogether she was a pitiable object.

Vaginal examination caused her great pain. The vagina was congested, swollen, and bathed with a creamy leucorrhœa. The cervix, of course, was large, soft, congested, and the os patulous. From the latter a stringy muco-purulent leucorrhœa was exuding. No blood-staining either by digital or speculum examination. Vesical examination, made by means of a soft rubber catheter only, was accompanied with the most intense pain. The urine was drawn at the time of the examination into a clean cup. There was not quite three ounces all told, and it was ammoniacal, bloody, and full of sediment. Upon examination I found it to be highly alkaline, of low specific gravity, and responding to test for albumin. The presence of the albumin was clearly due to the blood and pus contained in the urine. The sediment was very abundant and consisted of pus, triple phosphate crystals, with red blood-corpuscles, and bladder epithelium.

Up to this time no word had been said, by either the patient or myself, even hinting at the possibility of her pregnancy; but upon close questioning I obtained an admission of the truth from her; she placing, however, the time of impregnation as somewhere from the middle to the last of March. In addition, she stated that she felt something like motion about September 1st, but did not know what it was. Felt the same sensation a very few times between that and October 6th, and since then a great many times. Upon further inquiry I found that during her entire pregnancy she had worn her corsets and clothing as tight as she possibly could, and that for the few weeks previous to her coming to me she had not taken her corsets off night nor day. And further, that on September 5th she walked during the day some nine miles, visiting the State House, Des Moines, Ia., and climbing to the top of the dome; later in the day attended the State Fair, and in the evening a concert. On the 6th she walked fully ten miles, attended the fair again, and in the evening another concert. She wore upon both of these days a heavy velvet gown, which had been tight for her before her pregnancy, and which she could not fasten herself. The aid of a friend was required, who, in order to fasten the dress was obliged to pull upon the corset-laces with all her strength. I directed that her corsets be removed, clothing all loosened, ordered an immediate laxative and prescribed one-gram opium suppositories, as necessary to relieve pain, insure quiet in the recumbent position, and sleep. As she lived in a comparatively small town, where one's neighbors are disposed to make one's business their own, the patient was afraid to have me visit her at her home, but promised to keep me informed through her sister, as I told her she must not come to me, but must keep quiet. Her own family were at this time in absolute ignorance of her condition, but knew that she was ill, and her father had told her the morning of her visit that either she must see a physician or he would call one in. This brought her to me.

I saw her again on October 18th, with her father, to whom she had told her story the night previous, to arrange for her care until after confinement, in order that nothing should be known of her trouble. Her physical condition was the same as I have described. Condition of the urine just the same. Under the influence of the opium she had been able to lie down, and had slept for the first time since October 9th. Her bowels had moved freely in response to the sulphate of magnesium administered the day before. From the 18th to the 22d I did not see her, but her sister reported to me every day and brought me a specimen of the urine to examine. Incontinence persisted, and condition of urine was unchanged. Every day she had fever. As arrangements were pending to put her in a private hospital where I could have full control over her, I did not insist upon visiting her as I otherwise would have done. I continued the use of the opium suppositories, kept the bowels open, gave emollient drinks, and insisted upon quiet and rest in the recumbent position, to the furthest extent possible. The symptoms all persisted, and the only comfort she had was when under the influence of the opium.

On the evening of the 22d I was called in to see her. I found that labor pains had set in and that the os was sufficiently dilated to allow of the admission of my finger. The pains had first been felt in the morning of that day. Her body and clothing were in the same condition as when I first saw her, and incontinence continued. Pain upon lying down was but little modified. Upon examination found urine the same as heretofore described. Continued the opium in full doses and ordered her to keep very quiet. During the 23d saw her some three times. Condition unchanged. Os dilating and feet presenting. At nine o'clock I visited the patient, accompanied by a nurse, whom I placed in charge. I remained in the house and saw the patient from time to time during the early part of the night. Labor progressed slowly, and between 4 and 5 A.M., October 24th, she was delivered of a still-born male child. The child was undoubtedly asphyxiated during birth, and all efforts at resuscitation were of no avail.

It was at least an eight months' child, but I could not obtain any reliable data as to time of impregnation. The history, the presence of the child so low down in the abdominal cavity, and the fact that motion had not been felt until September 1st, had all misled me at the time of her first visit, and I had not thought her nearly so far advanced. There was no trouble after delivery. Uterus contracted well, and the lochia was normal in amount and quality during the puerperium. Following the delivery the urine dribbled continuously until 10 A.M. After it ceased dribbling there was no desire to evacuate the bladder; but when the nurse, at proper intervals, urged her to try, she passed a small quantity of urine, the character of which was unchanged. Great pain upon emptying the bladder, and afterward. At 8.30 A.M., temperature, 100° F.; pulse, 92. 6 P.M., temperature, 100.2° F.; pulse, 74.

October 25th.—No incontinence, but paralysis of sensation continued. No consciousness of urine in the bladder, but passed it when urged by nurse. Character unchanged. At 8.30 A.M., temperature, 99.4° F.; pulse, 68. 6 P.M., temperature, 100° F.; pulse, 76.

October 26th.—No change from preceding day. Urine still bloody and marked pain as before. Ordered the nurse to wash out the bladder, both in the morning and the evening, with a tepid saline solution. This was followed by some relief as to pain. 7 A.M., temperature, 100.2° F.; pulse, 72. 7 P.M., temperature, 100.4° F.; pulse, 94.

October 27th.—Condition unchanged. Bladder washed out morning and afternoon, as day before. At 5 P.M. she expressed a desire to empty the bladder for the first time since confinement. Passed water; then again at 6.30 P.M. and at 2 A.M. 7 A.M., temperature, 100.2° F.; pulse, 84. 7 P.M., temperature, 100° F.; pulse, 80.

October 28th.—Bladder irrigated as before. Patient

had desire to urinate at proper intervals. Pain somewhat less, but character of urine scarcely modified. 7.30 A.M., temperature, 99.4° F.; pulse, 72. 6 P.M., temperature, 100.6° F.; pulse, 84.

October 29th.—Began giving an infusion of buchu in connection with the flaxseed-tea, which she had had from the first. Bladder irrigated as before. Urine just the same. Complained of a great deal of vesical soreness and pain. 6.30 A.M., temperature, 99.4° F.; pulse, 74. 6 P.M., temperature, 100.2° F.; pulse, 80.

October 30th.—Directed the nurse to wash out the bladder with a pint of a two and a half per cent. solution of carbolic acid after the usual irrigation. This was followed by intense pain, tenesmus, and a profuse discharge of mucus. Ordered an opium suppository, which was followed by speedy relief. 6.30 A.M., temperature, 99.4° F.; pulse, 80. 6 P.M., temperature, 100.4° F.; pulse, 88.

October 31st.—Passed fourteen ounces of urine since 9 P.M. of previous day. At 2 P.M. passed eight ounces of urine. Very much less pain. Condition of urine markedly improved. 6.30 A.M., temperature, 99° F.; pulse, 82. 7 P.M., temperature, 100° F.; pulse, 84.

From this time on the patient steadily improved. All the evidences of cystic trouble disappeared, and by November 3d she was sitting up. From October 31st the temperature never rose above 98.4° F. but once, and then on the evening of November 3d, when it was 99° F. On November 6th she was able to get along without her nurse, and was walking about her room, waiting upon herself, with the assistance of her sister. During the first forty-eight hours, seven five-grain doses of antipyrine were given, both on account of the slight febrile disturbance and for its influence upon the lacteal secretion. There was no trouble with the breasts from first to last, and scarcely any milk secreted. Bowels were kept open by means of enemas, with an occasional laxative, and warm vaginal douches were given during the convalescence. I saw the patient last, professionally, December 11, 1888. She was entirely well, with no evidences whatever of the terrible experience she had been through save a slightly lacerated cervix. From that date up to May 1, 1890, I saw her at frequent intervals upon the street, apparently well.

As I have intimated, this case is not presented with the idea of its being of interest so far as treatment was concerned, but solely from an etiological stand point. It is well enough to say vesical hæmorrhoids or varix of the bladder, but they do not come without a cause.

Here was a healthy, well-developed girl who became illegitimately pregnant. She could see nothing to do but to conceal her condition from everyone, hoping, no doubt against hope, that something would happen ere the *dénouement* to save her from disgrace. To this end she wore her clothing as tight as was in her power, encasing herself at last in a gown of great weight, which had been tight for her before becoming pregnant, and which defied all her power to fasten. In addition, her corsets were worn continuously. On September 5th and 6th, dressed in this way, she was almost continuously on her feet from early morning till late at night—standing, walking, climbing—thereby doing what few American women, properly dressed, can do without more or less suffering. In addition, and in consequence of her habits, she was habitually constipated.

The question of traumatism, other than the long-continued one produced by her mode of dress and habits of life, will naturally arise in the minds of some, but that neither mechanical nor chemical traumatism existed I was absolutely positive.

Turning to the anatomy of the bladder we find that its vascular supply is very free, being derived from the superior, middle, and inferior vesical arteries and branches from the uterine artery. These all arise from the anterior trunk of the internal iliac artery. The anastomoses of the arterial twigs are numerous and free. The veins are also numerous and large, forming, by interlacement and connection, thick tortuous plexi about the base, sides, and neck of the bladder, and finally terminate in the internal iliac veins. The plexus about the neck of the bladder communicates with that of the labia minora, uterus, and rectum, and these are the chief elements in the so-called hæmorrhoids of the bladder. It is, of course, the venous part of the vascular system which concerns us here. Pregnancy itself tends to cause a condition of venous congestion.

Query? Was there not induced a varicose condition of the vesical veins because of the constriction about the waist, and the consequent downward pressure not only of all the abdominal organs, but of the gravid uterus as well. That this constriction and downward pressure were produced by her manner of dressing goes without saying. I read it thus. Constriction about the waist, especially over the liver, prevented return of blood from the valveless ovarian and hæmorrhoidal veins, thereby inducing a condition of blood stasis in them; pressure of the gravid uterus, both on the common iliac, which has no valves, and the veins which terminate in it, caused the veins of the bladder to become so distended that at last they ruptured, and hemorrhage in the bladder, with formation of clots, was the one result, and vesical paralysis from the steady downward pressure the other. For three days the hemorrhage and incontinence persisted. Then the passage of blood and clots, independent of the urine, stopped; but incontinence with bloody urine remained, and symptoms of vesical inflammation—chills, fever, pain, with mucus and pus in the urine—supervened.

That the hemorrhage into, and presence of clots in, the bladder set up an irritation which, with a possible exposure to cold induced the cystic inflammation, there can be no doubt. The case was one of great interest to me, and added but another to the already over-burdened list of reasons why women should clothe their bodies in accord with both anatomical structure and physiological function, not to speak of artistic fitness. True, it may be said that this is an extreme case. But may we not well question whether the influence of woman's mode of dress, and habits of life as well, are not productive of many of the vesical symptoms which are laid down in our obstetrical text-books and obstetrical teaching as a part of the necessary pathology of the pregnant state. That we get from a slight vesical irritability to very grave cystic troubles in pregnancy, there is no doubt, and while it may not be possible to do away with them entirely, I believe that proper dressing and right living would be productive of marvellous results in this direction.

And then a pregnant woman may so clothe herself, with loose and flowing garments, as to not only be artistically dressed, but healthfully as well, and enabled thereby to conceal her condition from the casual observer, rendering it possible for her to pursue her usual avocations and to take the out-door exercise which many a pregnant woman foregoes because of her sense of modesty. The conventional dress of the woman of to-day emphasizes her condition and forces attention thereto.

143 West Thirty-fourth Street.

Aseptic Tongue Spatula.—Dr. E. L. Oatman, of Nyack, N. Y., writes: "In addition to the danger of contagion connected with a universal tongue depressor, its use is so suggestive as to be resented by many patients of delicate sensibilities. To obviate these objections I have for a number of years, in ordinary throat examinations, employed cheap wooden spatulas which, once used, are immediately thrown away. The best wood for the purpose is maple, sawn into strips one inch in width by one eighth of an inch in thickness, which are then cut into six inch lengths. The rough surface as left by the saw-teeth gives the spatula an excellent 'hold' on the tongue. They are readily made at any planing mill for a trifling cost per thousand."

EXPERIENCE WITH TRICHLORACETIC ACID IN TWO HUNDRED CASES OF AFFECTIONS OF THE THROAT AND NOSE, WITH DEMONSTRATION OF INSTRUMENTS.[1]

By J. W. GLEITZMANN, M.D.,

PROFESSOR OF LARYNGOLOGY AND RHINOLOGY IN THE NEW YORK POLYCLINIC.

At a previous meeting of the Laryngological Section of the Academy of Medicine I mentioned, in the course of a discussion concerning the use of the galvano-cautery in diseases of the nose, that I had begun applying trichloracetic acid for similar purposes. I stated at the time, that the effect of the remedy had been very satisfactory to me and that it encouraged further experiments. I now beg leave to lay before this body the results of my investigations, as this caustic has proven in my hands a very valuable addition to our materia medica, and deserves a more extended trial by other observers.

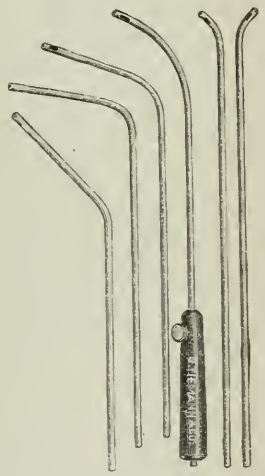
The application of trichloracetic acid in throat and nasal affections is of recent date. As far as the writer is aware, Dr. Ehrmann was the first to publish an account of experiments on one hundred and forty patients in the *Munich Medical Weekly* and the *New York Medical Monthly* in the spring of this year. In his papers he states that his attention was drawn to the remedy by Dr. Stein, of Moscow, who demonstrated to him and others the application of the caustic in turbinated hypertrophy in the throat clinic at Heidelberg. He finds trichloracetic acid superior to chromic acid, and claims excellent results from its use.

As to its chemical composition, trichloracetic acid belongs to the group of acetic, or more properly speaking of glacial acetic acid, and is an addition-compound of the latter and chlorine. The chemical formula of glacial acid is $C_2H_4O_2$, and there exist three addition-compounds of the acid and chlorine. In each of them the chlorine displaces one or more atoms of hydrogen. The formula for monochloracetic acid is therefore $C_2H_3ClO_2$, for bi- or dichloracetic acid $C_2H_2Cl_2O_2$, and for trichloracetic acid $C_2HCl_3O_2$. This chemical composition, viz.: the preponderance of the chlorine at the expense of the hydrogen, explains the difference of action of trichloracetic and glacial acetic acid. Both are strong caustics, but whilst the eschar of the latter is voluminous and its application generally followed by reactive obstruction, the eschar of the former is dry, firmly adherent, and the cauterization as a rule accompanied by no unpleasant symptoms.

Trichloracetic acid is sold in white crystals, which are readily soluble in water and alcohol and extremely hygroscopic. Merck's preparation, which I exclusively employed, is furnished in one-ounce bottles, and, to prevent its deliquescence as much as possible, it is advisable to take a small part of the acid from the vial and to put it into a smaller bottle for daily usage. This precaution was found necessary, as even when working with thoroughly dry instruments the frequent exposure of the crystals to the air when opening the bottle is sufficient to liquefy them. To further retard their melting too rapidly I made use of applicators, which I employed for several years in cauterization with chromic acid, a method which also had been adopted by Ehrmann. The instrument consists of a simple rod, which is best made of flexible material, and has an excavation at the distal end. The acid can be rubbed into the excavation by quick movements, leaving the bottle open only a few seconds. In this manner I succeeded in using up a whole ounce of the acid, without losing any by its hygroscopic tendency. The acid remains in the excavation of the applicator, and after the crystals accumulating on the lower end of the rod have been wiped off with cotton, the cauterization can be made.

In course of time it was found advantageous to add for certain purposes an eye at the side of the rod, as this assured a more rapid outflow of the acid and its quicker action. The rods recently improved and manufactured by Messrs. Tiemann & Co. I herewith present to the section. They are made of aluminium, which will not corrode by contact with the acid, and are moderately flexible, thereby allowing of any desirable curvature, if we do not wish to have a separate instrument for each application.

They are six in number, three for the nose, one for the base of the tongue, and two for the larynx. Two nasal applicators have eyes, one for the right, the other for the left inferior turbinated, the third with the nasal curve serves for cauterization of the middle turbinated, the fourth I used for hypertrophy of the lingual tonsil, and the laryngeal with the eye on its posterior surface for the interarytenoid space, the last one for other applications to the larynx, vocal cords, etc. The slight curve on the nasal applicators for turbinated hypertrophies I found useful for reaching and cauterizing their posterior surface. By carrying the distal end of the rod over the turbinated body and



then lowering it, the posterior portion of the hypertrophy is cauterized, without pressing the applicator through the sometimes narrow space between the septum and the turbinated. As all the acid is confined to the excavation in the applicator, a cauterization of other parts, which we wish to leave untouched, is thereby avoided, provided the rod is thoroughly dried with cotton before its introduction. Of course these instruments are capable of all possible alterations to suit individual cases and the predilection of the practitioner, but the applicators shown have fulfilled all desirable wants in my hands.

The pain produced by cauterization in the pharynx is insignificant, and neither children nor delicate nervous adults require any previous application of cocaine. The nose being a more sensitive organ, a ten per cent. solution of this drug is best employed before the introduction of the acid. As the applications of the acid to the larynx—at least as far as my experiments with it are concerned—were confined to certain localities, and as it was desired to avoid contact of it with other parts, the larynx was thoroughly anæsthetized with a twenty per cent. solution of cocaine, thereby localizing the effect of the acid, and avoiding pain and laryngeal spasm.

The eschar which is formed I found to be uniformly the same in appearance. As mentioned before, it is white in color, smooth on its surface, and in by far the majority of cases dry. This latter quality is a great advantage of the acid, in as much as it does not spread to other tissues, as do other similarly deliquescent caustics,

[1] Read before the Section on Laryngology and Rhinology of the New York Academy of Medicine, December 23, 1890.

for instance, chromic acid. But the most agreeable feature of the acid, which in my opinion is also due to the dry nature of the eschar, is the absence of inflammatory swelling and unpleasant after-effects. The applications to the pharynx and larynx under cocaine produce no manifestations whatsoever, and after cauterization of nasal hypertrophies only a small number of patients experience a mild, short-lasting coryza. The eschar remains generally from two to five days, after which time it is either expelled or can easily be detached with suitable instruments. Regarding the exceptions to this rule I shall make some statements after having given a résumé of the cases which form the basis of my paper.

My observations extend over 200 cases, which with one exception were treated in private practice from April 29 to December 1, 1890. In addition, a considerable number of patients were treated during this time at the dispensaries to which I am attached, but as it was impossible to keep accurate records, they could not be used for our purpose. The age of the patients ranges between six and seventy, 109 were males, 91 females. As several patients suffered from afflictions of more than one locality, the number of applications to different parts is somewhat higher, viz., 227. In the beginning I confined myself more to affections of the nose, but after my return from Europe in the fall, I gave the remedy a wider range and extended its use to other lesions, which I expected to be favorably influenced by its action. The diseases in which trichloracetic acid was employed, were: 170 cases of hypertrophic conditions of the nose, 25 of hypertrophy of the lingual tonsil, 6 of hypertrophy of the faucial tonsils, 12 of granular pharyngitis. Two applications were made to cartilaginous spurs of the nasal septum; one to a perforation of the system with scab formation; one with the intention of lessening excessive secretion of the nasal chambers without any other demonstrable disease; three to the interarytenoid space; two in phthisical subjects; one in a patient with pachydermia of the larynx, and seven times a cauterization was made to the wound produced by the galvano cautery, with the expectation of obtaining a dry eschar and thereby lessening the subsequent swelling and reaction.

Although not strictly belonging to the scope of this paper, I will mention that I applied the acid in two cases of aural polypi with success in one patient, who allowed the treatment to be carried out, while the other was treated only once.

As one is always in danger of becoming too enthusiastic when advocating and experimenting with a new remedy, I was very careful to take notes of failure or unsatisfactory results, when such took place. It will be my endeavor in analyzing my records, to point out to you the deficiencies and shortcomings I experienced, in order to enable you to form an unbiassed opinion about the efficiency of the remedy.

Instead of taxing your patience with an array of histories of cases, which do not present any special interesting features, and the symptoms of which are all familiar to you, I shall confine myself to give a résumé of the groups of diseases enumerated above, and only refer to details when occasion calls for. I shall leave the analysis of pharyngeal and nasal hypertrophies for a later consideration, and begin with those affections in which the smallest number of applications have been made, and where the larger number of failures have to be recorded.

Trichloracetic acid had little or no effect when applied to cartilaginous spurs of the septum or to an artificial septal perforation, on the edges of which large crusts had been constantly forming. In neither case an opportunity was offered to continue the treatment long enough to give it a fair trial, but from what I could learn, especially from one case, I am inclined to believe that the acid makes very little impression on cartilage. The case of rhinorrhœa was treated for experiment's sake only in the hope that the dry eschar generally formed by the acid might bring on some tissue change, and in this manner decrease the secretion. As this effect was not produced, other means had to be resorted to.

Of the three patients treated for affections of the interarytenoid space, one case cannot be considered, as only one application was made. One phthisical patient, whose vocal cords were intensely hyperæmic, but whose larynx showed no ulceration nor extensive infiltration, presented a honeycombed, thickened surface of the posterior wall, interfering with complete closure of the glottis posteriorly, and thus causing hoarseness. Two applications of the acid in the interval of twelve days were followed by a healthy appearance of the parts, and, in conjunction with treatment of the vocal cords, materially improved the voice. The same result was obtained by three applications in a dispensary patient, suffering from a dense and hard infiltration of the interarytenoid space. Although not mentioned in the above list, I may state that I have also at present under observation and treatment, a patient with a small papilloma of the right vocal cord, which has decidedly decreased in size by cauterization with the acid. These four cases are too few in number to draw any definite conclusions, still I cannot but help express it as my belief that this remedy is destined to be used more extensively in the larynx. The larynx is an organ in which it is desirable to confine, in many cases, the application of a caustic to a circumscribed locality. Trichloracetic acid forms a dry eschar at once, which prevents it from spreading to other parts. Another of its features which is especially valuable in the larynx, is the absence of all subsequent swelling and reaction, which we observe frequently with the use of the galvano-cautery in the larynx. Localized infiltrations of the mucosa of the vocal cords, which we sometimes see in catarrhal conditions, small growths, ulcerations, also infiltrations, can, in my opinion, be successfully treated with the acid. If Koch's method does not abolish the endolaryngeal treatment of laryngeal phthisis, patients who cannot be subjected to the surgical treatment will find relief by the judicious use of the caustic.

The number of patients treated for granular pharyngitis and hypertrophy of the faucial tonsils is small and out of proportion with the total number. In both instances I could not overcome my predilection for the galvano-cautery, which, with proper precaution, gives but little after-pain and assures quicker results. But with the patients suffering from granular pharyngitis and treated with the acid, success was obtained in by far the majority of cases, and only a few applications (from three to four) were necessary to bring on reduction of the granulations. Five patients had simple granular pharyngitis, and seven so called lateral pharyngitis. In the latter class, in which the galvano-cautery is generally followed by pain and discomfort, no unpleasant sequelæ were observed. Tonsillar hypertrophy seemed not to yield so readily to the caustic, and required a larger number of applications. Two patients did not complete their treatment, and were seen only twice; in the other four a thorough reduction of the tonsil was effected. In one of these, a professional singer, thirteen applications of the acid were necessary to achieve the desired end, and they were made on account of the positive objection of the patient to the galvano-cautery. In such cases I consider the acid one of our most valuable means to destroy the hypertrophy, but I find, contrary to the observations made by Ehrmann, that the galvano-cautery in pharyngeal, as well as in nasal, hypertrophies, is superior to the acid in efficiency, and that a larger number of applications of the latter are necessary to accomplish our purpose.

I gave trichloracetic acid a thorough trial in hypertrophy of the lingual tonsil and have the records of 25 patients. Five patients were cauterized but once and are therefore left out of consideration, in 8 the galvano-cautery was used in addition, leaving 12 cases which were treated with the acid only. To these 12 patients altogether 74 applications were made, an average of about six; the smallest number producing a favorable effect was 2, the

largest one made was 18, which were made to the same patient, requiring 13 applications to her faucial tonsils. The majority of the 20 patients were discharged cured, 6 are still under treatment, and with 2 exceptions all are more or less benefited. One lady was cauterized twice, but did not experience any relief from the scratching and burning in her throat. The other patient, although presenting a well-marked lingual hypertrophy, only got rid of the burning and sensation of pressure in the throat after an energetic scarification of his faucial tonsils. A few of the cases in which the acid and galvano cautery were used conjointly deserve mention. A former student of mine at the New York Polyclinic who complained of dryness in the pharynx necessitating constant clearing of the throat, expressed himself as feeling very much better after the first application. As he desired to return home without much delay, the remaining portion was destroyed with the galvano-cautery. A lady who suffered several years from a dry, spasmodic cough with occasional hoarseness, presented at inspection a large, grape-like hypertrophy in the median line, touching the edge of the epiglottis. The growth being too large to yield readily to the acid, was snared off with the irido platinum wire, and the rest treated with trichloracetic acid with the most gratifying result. I have a letter from the husband of another lady, who is at present confined to her house on account of illness, that her throat is greatly relieved. She also was troubled with tickling in her throat and a most harassing cough, and two applications with the acid were made. I cannot conclude this chapter without alluding to the history of a patient, who for the last eight years was troubled with an incessant desire of swallowing. If I had not been aware that so-called empty swallowing is one of the symptoms of lingual hypertrophy, I would probably have overlooked the organ entirely, as only insignificant small nodules and a few varicose veins appeared on its surface. The effect of the first application was marvellous, and elicited the most eulogistic remarks on his part. As he is not cured yet entirely, the applications are continued, although only a few enlarged veins are visible at present.

In turning to the last subject of my paper, the treatment of nasal hypertrophies, I must state at the onset that it is impossible with the time at my command to analyze the individual cases as thoroughly as it had been done in the previous chapters. Before going into details I wish to mention another experiment I had used the acid for. There are a number of patients who present a stenosed condition of the nostrils without deviation of the septum or true turbinated hypertrophy. Similar conditions sometimes remain after correction of a deviated septum, and I often found it a tedious undertaking to establish a free opening. In three cases of this nature I attempted to dilate the nostril by introduction of the acid to the stenosis, but soon found that the result was decidedly less satisfactory than with the use of my tupelo tents, and therefore desisted from further trials.

Among the 167 cases remaining 5 had hypertrophic conditions arising from the nasal septum, of the balance 47 were treated but once, leaving 116 patients who were cauterized more or less frequently. The number of applications ranged between 2 and 14, and in one case being as high as 20. This patient, previously subject to repeated and violent attacks of sneezing, had made daily use of cocaine to the nostrils during an interval of treatment. The employment of the galvano-cautery being inopportune on account of extrinsic reasons, it required prolonged and extraordinary efforts to destroy the large and dense hypertrophies. The average number of applications to promote decrease or destruction of turbinated hypertrophy of one side, is about four. It is to be expected that with the introduction of the new instruments shown to the section, the number of cauterizations necessary will still be lessened, as the applicators of the old style, which I have been using till a month ago, have no eye and a smaller opening, therefore taking up and giving out less acid. Although favorable results were the rule and in a fair proportion followed already after two applications, it was found that a number of patients required more energetic measures, and with twenty-two the galvano-cautery was used besides the acid. On the other hand trichloracetic acid proved effectual with two patients who previously had been treated with chromic acid, which I have entirely abolished in my private practice during the time of these experiments.

In no locality where trichloracetic acid had been employed are its advantages over other remedies in regard to the small degree of discomfort following its usage more obvious than in the nasal passages. As stated before there is no consecutive swelling, no inflammatory reaction, the dry eschar remains firmly adherent to the parts and guards them against infection. The patients can leave immediately after the application without any subsequent dressing or cleansing of the cauterized surface and require no home treatment at all, a feature which cannot be appreciated too highly.

The time the eschar requires for its elimination is, as previously mentioned, from two to five days, but differs also sometimes in the same patient when two turbinated bones are cauterized. I have kept memoranda of this condition in a number of cases, and observed that in two patients the eschar had disappeared in one nostril after two and three days respectively, while it was adherent in the other, both nostrils being treated on the same day. In two cases, one of which was the patient requiring twenty cauterizations, I could never detect an eschar after two days. It is remarkable that with the large number of applications made, only two patients were found who suffered from unpleasant after-effects, similar to what we were prepared to see after the use of the galvano-cautery, glacial acetic acid, nitric acid, etc. One was a girl of fourteen, the other a man of forty years of age, both of a highly nervous temperament. In each instance the eschar was moist, swollen, and filled the larger part of the nostril. Fulness of the nose and copious liquid discharge, resembling acute coryza, were the natural consequences. After four days these symptoms subsided, but reappeared with a subsequent cauterization.

I cannot close this chapter without alluding to another use of the acid, although I had but just commenced experimenting when I received the request of our Chairman to read my paper this evening. My observations are of too recent a date and too few in number to allow of any definite conclusions, and I therefore mention them only in the hope that they will be taken up by others and their value determined. In a paper read before the last International Congress, and in an article published in the *Therapeutic Monthly*, of October, Bresgen, of Frankfort, recommended pyoctanin after galvano-caustic operations in the nose. I have no personal experience with his method, but tried trichloracetic acid for the same purpose, viz., to prevent subsequent swelling and reaction. I operated seven times on six patients for hypertrophy of the inferior turbinated. In four cases the eschar remained perfectly dry, and could easily be detached on the fourth day. Twice it became soft and created considerable liquid discharge from the nostril without causing obstruction. One patient, on whom one turbinated had been operated upon successfully, suffered from stenosis and headache after the second operation during the following day, and was completely relieved by removal of the eschar on the third day. No home treatment was adopted in either case, and no dressing of any kind was used. It is to be expected that with the proper use of trichloracetic acid the unpleasant symptoms often following galvano-cautery applications will be considerably lessened.

In summarizing my paper I beg to offer the following conclusions :

1. Trichloracetic acid compares favorably with other caustics in hypertrophic conditions of the throat and nose, and is a valuable addition to the remedies now in use.

2. In the greatest majority of cases it is sufficient to produce the desired reduction of tissue, although it does not supersede the galvano-cautery.

3. It can be applied with safety to the larynx without any evil consequences.

4. Its chief advantage in nasal affections is the dryness of its eschar, which prevents unpleasant sequelæ and makes after treatment unnecessary.

117 Second Avenue.

THE USE AND ABUSE OF DRAINAGE IN SURGERY.[1]

By JAMES E. MOORE, M.D.,

PROFESSOR OF ORTHOPEDIC SURGERY IN THE UNIVERSITY OF MINNESOTA.

The besetting sin of our profession is our tendency to go to extremes. We discover something the judicious use of which would be of untold value to the human race, and are not content with its proper use, but must needs overuse it until its use becomes an abuse, when a reaction sets in and abuse is many times followed by disuse. In the matter of drainage of wounds we are still in the stage of abuse. Reaction has already set in, and inasmuch as proper drainage is such a vital part of surgery, it is our duty to study the subject carefully and not allow disuse to follow abuse. This reaction first began in abdominal surgery, and already we have learned that in a certain class of cases in which we at one time thought drainage an essential, we get the largest percentage of recoveries without drainage. Laparotomists have pretty nearly arrived at the truth, viz., that septic cases and doubtful cases should be drained, and that aseptic cases are better without drainage. I fear that in this important branch of surgery the reaction has a tendency to go too far, and that certain cases are left without drainage that would be better with it. We can also see some reaction in amputation wounds, where, instead of the sewer pipes of former days, we use drainage tubes of smaller size, or none at all.

We, as members of the grandest profession on earth, have weighty responsibilities, and are held strictly accountable for our deeds and misdeeds, but being only human beings are entitled to the privilege of changing our views with increase of knowledge. In fact this is the only way we can advance. The very fact that our responsibilities are such weighty ones should remind us that we should guard against our besetting sin and avoid extremes. This can only be done by refusing to accept the *ipse dixit* of any man, no matter how exalted his position may be, and by basing our change of views upon facts, instead of following in each other's wake like a flock of sheep.

The thorough drainage of wounds has been considered of primary importance for many years, but when Chassaignac suggested the use of drainage-tubes in 1855 his reason for draining was very different from that of the surgeon of 1890. He drained to allow of the free escape of pus. We drain in recent wounds to prevent the formation of pus. The necessity for drainage in an infected or suppurating wound is universally understood. The more perfect the surgeon becomes in his antiseptic methods the less he needs drainage-tubes and their various substitutes, and when he arrives at that stage of perfection in his methods that insures him an aseptic wound every time he operates he can dispense with them altogether. In all recent works on surgery we are advised to use drainage-tubes to carry off the excessive discharges from a wound, but we are not advised to make an opening at the seat of a fracture to carry off the discharges. Those who first learned of the value of drainage in open suppurating wounds, also learned that Nature took care of the discharges from a subcutaneous wound. When we have so perfected our methods of wound-dressing that we can place an open wound in the same condition as a subcutaneous wound we will no more think of draining in one any more than in the other. If a wonnd is aseptic Nature will take care of the discharges, just as she does in a subcutaneous wound. In a simple fracture of the femur there is much greater effusion of blood and serum than in any operation wound, and we never think of draining it off. Nature takes care of it promptly, the only disturbance being a transient rise of temperature.

Twenty-five years ago surgeons drained to carry off the pus. Fifteen years ago they drained to carry off the discharges so that they would not putrefy. At the present time we drain largely from force of habit. We no longer believe in spontaneous generation, or that the discharges putrefy without first having been infected from without. Blood in an aseptic wound becomes partly absorbed and partly organized. Serum should not be looked upon as something to be gotten rid of, for it undoubtedly has an important function to perform in the reparative process. In certain cases that we are learning more about every day, viz., infected cases, we must always drain. I maintain, however, that in aseptic cases drainage by means of rubber or other open tubes is not only useless but adds an element of danger. We learned the value of drainage when septic surgery was practised, and notwithstanding the fact that our reasons for drainage have undergone very radical changes, we have been using drainage-tubes too nearly like we did at first. The principal difference is, that we originally allowed the drainage tubes to protrude through the dressings, thereby infecting every wound. We are now very careful to cover the ends of the tubes and to allow everything to pass out, and nothing to pass in through them, which is an exceedingly difficult matter. Aside from the fact that a drainage-tube is a foreign body and interferes with primary union, the one great danger is that it keeps an entrance-way open through which germs may enter and infect the wound.

It is customary to close small wounds in all parts of the body without drainage with very satisfactory results. I can see no reason why a large wound should require drainage any more than a small one, for the amount of absorbing surface bears the same proportion to the discharges in the one as in the other. I believe we have allowed the size of the wound to influence us too much when deciding whether to drain or not. The character and not the size of the wound should decide the question. I fear that we have fallen into the habit of draining every wound without thinking whether it is necessary to drain or not.

I was first led to question the propriety of draining every large wound by the annoyance occasioned by rubber drainage-tubes after operations upon tubercular joints. I found that the sinus caused by the drainage-tube almost invariably became infected and prolonged the case unnecessarily. Although I still drain in cases of this kind when there is a possibility that I may have overlooked some focus of disease. I never use rubber tubes, but use strips of iodoform gauze. In excision of the knee joint my happiest results have been in cases where I have omitted drainage altogether, or have used a few strands of catgut. I get more satisfactory results after amputations, after operations upon breast and axilla, and in fact in all clean-cut wounds, without drainage than with it. No one prizes drainage more highly than I in proper cases, but it is not necessary in an aseptic wound. Those who do not work antiseptically must always drain, because blood and serum when not protected from germs will surely putrefy in a wound, where all the necessary auxiliaries are found. The most zealous advocates of drainage are those who denounce antiseptic surgery.

It would be amusing were it not such a serious matter to see how zealous a dirty surgeon is in the matter of drainage. He usually carries his rubber tubing in the bottom of his satchel, after taking it from a dusty drawer

[1] Read before the Hennepin County Medical Society at Minneapolis, January 19, 1891.

in his office, and if he has not infected his wound earlier in the operation, always does so when he introduces his tubes.

When carbolic acid was so extensively used drainage was always necessary, on account of the excessive discharge caused by the acid. Lister, in his address before the last International Medical Congress, said that it would be a grand thing if we could do away with drainage altogether, and cited an instance in which he uses but one tube of moderate calibre where he formerly used four of various dimensions. He speaks of the time when we shall have found drainage no longer necessary as the fulfilment of his early dream. If this great benefactor lives out his expectancy, I feel certain that he will see this day. The enemies of antiseptic surgery point to these advances of Mr. Lister's as evidence of its decay. But every fair-minded man knows that there has been no change of principles.

With all its perfections antiseptic surgery is far from being perfect yet, and many changes of detail are necessary, but these changes instead of being evidences of decay are certainly advances.

As Mr. Lister suggests, these advances are all in the direction of the hermetic sealing of wounds, and this is certainly the ideal method, as it is Nature's method. The hermetic sealing of wounds has been faithfully tried in the past, but the trial was made at a time when the principle of wound infection was undiscovered, and it was necessarily a failure.

Mr. Tait, in his criticism of Mr. Lister's address, claims everything for drainage. He says that when all decomposable material is removed by drainage, germs may be admitted freely. He states that the exclusion of germs is an impossibility, but does not seem to understand that perfect drainage is also an impossibility.

Professor Erichsen, in some recent remarks upon this controversy, has certainly sounded the key-note when he cites the fact that two elements are necessary for putrefaction in wounds, viz., putrescible material, and infective germs, and says that the disputants accomplish the same end by different means: Mr. Tait by removing the pabulum, and Mr. Lister by filtration of air and by germicides. He very wisely asks, "Is it wise to be exclusive in the employment of one or the other of these methods?"

I am certain that many wounds have been infected through the drainage-tubes because it was impossible to keep the ends of the tubes covered by the dressings. I have found it very difficult to keep the dressings close to the wound after radical operation for hernia, and have gotten much better results since I began to apply small strips of iodoform gauze with collodion.

In some operations upon bone, and in Phelps' operation for club-foot, special effort is made to secure a blood-clot in the wound, in order that it may become organized. Ordinarily, however, it is important to stop all hemorrhage before closing a wound that we do not wish to drain.

I wish to offer as proof of my position a very brief report of a few cases.

Case I.—Mr. M——, aged twenty-eight, had been suffering from an acquired talipes equino-varus for some years, and had gotten to be so helpless that he was referred to Dr. Hunter for amputation, who sent him to me hoping that I might overcome the deformity and save the foot. After having given ordinary orthopedic measures a fair trial, and finding that they were inefficient, I decided to follow the patient's suggestion to "make that foot toe out or cut it off." In May, 1889, at St. Mary's Hospital, assisted by Dr. Dutton, I applied an Esmarch from toe to knee, and made a free incision through all the soft parts on the inner side of the foot just in front of the malleolus—in short, did a Phelps operation. I found, however, that, owing to the extensive anchylosis in the tarsus, very little was gained. I then did a linear osteotomy through the neck of the astragalus, after which the deformity could be only partly overcome. I then removed a wedge-shaped piece from the outer side of the tarsus, after which the deformity was over-corrected. After thorough irrigation with a 1 to 2,000 solution of bichloride of mercury, a piece of rubber tissue was placed over the gaping wound on the inner side of the foot, leaving a large space to be filled with blood-clots. An antiseptic dressing was applied without drainage-tubes, and over it a plaster-of-Paris bandage. The last thing done was to remove the Esmarch and allow the wound to fill with blood. The next day the patient had a temperature of 101° F. At the end of a week he felt so well that he insisted upon going to his home in the southern part of the State. On July 4th he returned, and upon removing the dressings I found the wound perfectly healed and the foot in an excellent position.

Case II.—A lad of sixteen, who was suffering from a tubercular ostitis of the right knee, came to me in August last. At the Northwestern Hospital I made an excision of the knee-joint. There was much destruction of the soft parts, and several points of disease extended well down into the head of the tibia, so that there was a large wound surface and two good-sized cavities in the tibia. The patella was removed and the bones were nailed together with four steel nails. The usual antiseptic dressings were applied with only a few strands of catgut in either angle of the wound for drainage. A plaster dressing was applied. The patient never had a temperature over 100° F., and had no unfavorable symptoms. At the end of thirty days I found the wound perfectly healed and bony union taking place, and eight weeks after the operation I brought him before this society showing a perfect result. The first dressing was not soiled, showing that there had been no drainage.

Case III.—In July, 1890, at the Northwestern Hospital, I amputated a carcinomatous breast and removed all of the axillary glands from a patient aged thirty. No drainage. Perfect union of axillary wound by first intention.

Case IV.—In September, 1890, was called by Dr. Rochford to see a child, less than one year old, suffering from a strangulated inguinal hernia. With the Doctor's assistance I relieved the constriction and performed a radical operation. No drainage in either deep or superficial wound. After the fourth day all bandages were removed. The child made a perfect recovery in a much shorter time than would have been possible with drainage tubes. In this case I do not believe it would have been possible to have prevented suppuration with drainage-tubes, on account of the age of the patient.

I do not deem it necessary to cite a case of prompt recovery without drainage after laparotomy, because this is of everyday occurrence. Although I never drain after laparotomy without special indication, I have found it necessary to drain in many of my cases, because they have been those of the character coming under the care of a general surgeon rather than a gynecologist.

Excitability of Nerve-Roots.—Two Italian observers have recently related the results of a series of experiments undertaken to determine the influence which the posterior nerve-roots have on the excitability of the anterior roots. (*The Lancet.*) In the first series of experiments the posterior roots were treated with cocaine; in the second the posterior roots were divided; in the third the posterior roots were stimulated electrically; while in the fourth series the cord was divided below the medulla. It was found that when the posterior roots were rendered functionless the excitability of the anterior roots was diminished; but when the posterior roots were stimulated in any way there was produced an over-excitability of the anterior roots, which went on in a short time to diminished or even abolished irritability, and the same results were found when the cerebro-spinal system was intact and when the cord was divided below the medulla.

Progress of Medical Science.

The Recognition of the Gonococcus.—Dr. Steinschneider maintains, in opposition to a statement of Fürbringer's, that the application of the Gram method of staining micro organisms is necessary to the satisfactory study of the gonococcus, inasmuch as the only positive characteristic of this coccus is that it is not stained by this method, while nearly all other diplococci found in the urethra are colored thereby.

These conclusions, which agree with those of Roux, Allen, and Wendt, are the result of the examination of eighty-six patients with acute and chronic gonorrhœa. The almost entire certainty of this test is rendered absolute by the observation of the further character of the gonococci, namely, that they are found within the pus-cell.—*Centralblatt für die Med. Wissenschaften.*

The Blood and Urine of the Insane.—Dr. Smyth (*The London Medical Recorder*) has made a careful study on this subject. Four classes of patients have been subjected to examination and experiment, including subacute cases of melancholia, epileptics, general paralytics, and the subjects of secondary dementia. Epileptics have been studied under the conditions of freedom from fits, during or immediately after fits, and in three cases the examinations were conducted for thirteen days on a mixed diet, and for twenty days on a fixed diet. The most careful arrangements were made to insure accuracy and uniformity in the experiments, and comparisons were instituted with the blood of fifteen healthy men, aged between twenty-three and fifty years. In the case of epileptics there was an average diminution in the number of red corpuscles, and the same observation holds true also with melancholiacs and other insane conditions, the hæmoglobin being consequently markedly deficient as compared with what obtains in ordinary healthy individuals. The most conspicuous defect in this connection is, however, found in secondary dementia, the differences in amount in the three conditions of melancholia, general paralysis of the insane, and epilepsy being inconsiderable. It is shown also that the blood-plasma is especially dense among the insane, since, notwithstanding the deficiency of hæmoglobin, to which element the weight of healthy blood is greatly due, the difference between its specific gravity and that of the blood in insanity is extremely slight; hence the plasma must necessarily contribute to make up the weight-giving quality of the tissue. The variations in the other solid elements of the blood presented nothing much worthy of note, nothing of a constant character having been found in this relation. With regard to urine, Dr. Smyth finds that the amount of this fluid passed is greatest in general paralysis of the insane, in which it considerably exceeds the healthy standard, while it is least in secondary dementia. The total solids also are greatest in general paralysis, and least in secondary dementia, the variations being within small limits in the other diseases. The further conclusions arrived at in this connection are, that healthy men do not excrete more urea than insane patients; that in general paralysis, epilepsy, and melancholia, the urea seems almost equal in the amount secreted, though dements excrete less; that uric acid is increased in the excretions of the insane, being greatest in general paralysis, epilepsy, and dementia; that creatinine is higher in general paralysis and in dements than in health, and that phosphoric acid is in slight excess in epilepsy.

Differential Diagnosis of Diseases of the Blood.—According to Professor v. Jaksch, the first step is to make a simple microscopic examination of the blood. This enables us to recognize oligocythæmia, oligochromæmia, poikilocytosis, and leukocytosis, also leukæmia and melanæmia. Poikilocytosis is a condition, not a distinct disease; high grades of it occur in every case of advanced anæmia. The next step is to count the cells in a given volume of blood, and to determine the proportion between the red and white corpuscles by the Thoma-Zeiss apparatus, or that of Malassez as modified by Gowers. Thirdly, the hæmoglobin must be estimated by Heischl's or Henocque's apparatus. We may pronounce the case as one of anæmia when there is diminution of the number of red corpuscles, or a diminution of hæmoglobin. These two conditions usually coexist. If they do so in equal degree, we have simple anæmia, as after great loss of blood, or after various acute and chronic diseases. Characteristic of pernicious anæmia are the extreme progressive oligocythæmia, the diminution of hæmoglobin, and the increased size of the red corpuscles. Chlorosis affords nothing characteristic; the number of red corpuscles is apparently normal, but their hæmoglobin is less. Anæmia after severe malaria is recognized by Laveran's plasmodes contained in the red corpuscles, which disintegrate the latter and cause the formation of melanin. The blood-cell perishes here and there, and the melanin is set free, or is taken up by leucocytes. Leucocytosis occurs physiologically toward the end of digestion. It is found temporarily in acute pneumonia, especially in children, but is scarcely to be called characteristic of that disease. In pseudoleukæmia, the latter stages always show oligochromæmia, oligocythæmia, and a pretty high degree of leukocytosis, giving sometimes the aspect of leukæmic blood. Leukæmia is at first very difficult to diagnose; the behavior of the cells toward eosin may be an aid. In typical leukæmia there is an enormous increase of leucocytes, with diminution of red corpuscles, and great diminution of hæmoglobin. In the lienal form large-celled leucocytes predominate, in the lymphatic form the small-celled; while, if the bone-marrow participate, there are found extremely large leucocytes with large nuclei, numerous transitional forms between white and red corpuscles, and many cells with an affinity for eosin. According to the author, there is a form of persistent leukocytosis in children which, unlike leukæmia, often ends in recovery; it is characterized by diminution of red corpuscles and of hæmoglobin, pronounced leukocytosis, enormous splenic enlargement with but slight enlargement of the liver, and occasionally glandular swellings. It is distinguished from leukæmia by the almost total absence of eosin-staining cells, and by the contrast between the liver and spleen. It is distinguished from anæmia in rickets by the much higher degree of leukocytosis and its progression, also by the absence of rachitic signs.—*Prager Medicinische Wochenschrift.*

Microscopical Examination of Semen.—The amplification used should be not less than 400 or 500 diameters, or say a 2″ eye-piece and a $\frac{1}{8}$″ or $\frac{1}{10}$″ immersion objective, or a 1″ eye-piece and a $\frac{1}{4}$″ or $\frac{1}{5}$″ dry objective. It is true that the spermatozoids may be seen with much less amplification (a 2″ eye piece and a $\frac{1}{4}$″ or $\frac{1}{5}$″ objective showing them quite plainly), but the determination of the mere presence of the elements, even in great numbers, is not sufficient. We must in doubtful cases inform ourselves as to whether those that we find are possessed of their physiological properties, and especially the mobility necessary to penetrate the uterine cavity. De Sinéty states that in three cases examined by him (married men who had no children) the spermatozoids, though present in normal quantity, became immobile almost immediately after their ejaculation. Of course, this sort of an examination presupposes the freshness of the semen. The sooner that it can be placed under the instrument after ejaculation the better. A tentative course is necessary in most cases. The patient is given a couple of clean, ringed slips and cover-glasses, and is told that on the first opportunity he shall place a drop of semen on the slip and immediately apply the cover-glass and bring it to the examiner. The advantage of the ringed slip over the plain one is, that the semen may be kept fluid and normal therein for several hours, whereas the rapid drying

around the edges on the plain slip causes the cover glass to be drawn down very close to, and in fact almost into contact with, the surface of the latter, thus destroying all possibility of motion on the part of the spermatozoids. The slip should be examined at once. If the spermatozoids are found to be absent, no further examination is necessary. If they are found to be present, and normal as to quantity, it may be necessary to investigate further to determine the motility and vitality of the elements. In such cases circumstances must be the guide as to the method of obtaining a fresh specimen. It may be remarked here that when the semen is preserved in ice the movements of the spermatozoids continue much longer than when it is kept at normal temperature. It has been claimed (see "Proceedings of the American Society of Microscopists for 1886") that when put into a small tube, and the latter enclosed in a block of ice, the movements last for several days. The exceptional cases of aspermatism are those which may be called "physiological," in the sense that the absence is temporary and due to excessive coitus. In these cases the ejaculated matter comes entirely from the prostate (as shown by Feuerbringer in the *Zeitschrift für Klinische Medicin*. 1881, page 287), and is devoid not only of spermatozoids, but of the gelatinous hyaline matter secreted by the spermatic vesicles.—*St. Louis Medical and Surgical Journal.*

Epidemic Chorea.—An epidemic of chorea occurred some time ago in a German school. The particulars are given in a paper by Dr. Wichmann. Twenty-six children in all were affected, eighteen girls and eight boys, the girls being first affected, some more severely, some very slightly, while in all the boys the manifestations were slight. The patients continued to attend school, and there seems little doubt but that the contemplation of those who were affected with the disease had considerable influence in evoking the symptoms in the other children. This is confirmed by the fact that rapid improvement and subsequently complete restoration to a normal condition took place in those who were kept away from school.—*Deutsche Medicinische Wochenschrift.*

Treatment of Abscess of the Liver.—The following are the conclusions of an elaborate article, based upon the study of a large number of cases published by Dr. Jorge L. Rivas in the *Revista Médica de Chile*, November 11, 1890. 1. Whenever we suspect the presence of an abscess of the liver we ought at once to investigate by means of exploratory punctures which must, however, be strictly antiseptic in order to be safe. 2. It is not necessary, before an exploratory puncture be made, that there should be adhesions, but on the contrary this procedure is indicated when no adhesions exist as being an excellent means of exciting them. 3. These punctures are an excellent, and the only certain means of arriving at a diagnosis, and they are also often of assistance in prognosis and in determining upon the best method of treatment. 4. Aspiration by itself often suffices to bring about a cure, but in order to accomplish this it is very necessary to remove the pus as thoroughly as possible. All surgical treatment should begin with this procedure, except when there is absolutely no hope of obtaining a cure by this means, or when the general condition of the patient is so alarming as to admit of not the least delay. 5. When aspiration fails we must generally resort to antiseptic incision with a large straight bistoury. 6. The presence or absence of adhesions is of no importance in the matter of operating, for their presence is no indication, neither is their absence a contra-indication to the operation. 7. When the abscess is on the convex surface of the right lobe the incision should be made in the eighth intercostal space, and when it is situated on the concave surface the knife should enter about a finger's breadth below the free border of the ribs, and in both cases between the axillary and mammary lines. If the abscess is in the left lobe it should be opened in the presternal line about three-quarters of an inch below the ensiform cartilage; the incision should vary in length according to the necessities of the case from a little over an inch to five inches. 8. Alterative or antiseptic injections contribute to the successful result in cases of puncture, and are of prime necessity when a free opening has been made. In the first case the amount of the injected material ought never to exceed that of the pus removed. 9. Among the best of the alterative injections are Lugol's solution of iodine and chloride of zinc (two per cent.). 10. The preferable antiseptic injections are a two per cent. solution of carbolic acid and a three or four per cent. solution of boric acid. 11. The best treatment in most cases is the free opening of the abscess and thorough cleansing of the cavity, scraping the walls if necessary. 12. Drainage by simple tubes is preferable to that by Manson's syphonage, since the former permits of the changing of the dressings every eight days, and the injection of alterative solutions if desired. 13. Abscesses which have opened spontaneously into the pleural cavity, lung, intestine, etc., are to be treated in the same way by free opening under antiseptic precautions, the indication in such a case being of course more urgent than when the pus has not found exit.

Chloroform in Tracheotomy.—Dr. Geffrier has published a paper on chloroform in tracheotomy. The views of this author, which are based on a study of eighty-seven cases, may be summed up as follows: 1. Chloroform is of unquestionable service in tracheotomy on children. 2. Its use is not attended with any special danger in this operation, provided that attention be paid to certain contra-indications. 3. The following precautions ought to be taken: (*a*) Everything that might be required in the course of the operation should be placed close at hand. (*b*) The administrator, who ought to be experienced in the use of chloroform, should carefully watch the respiration, and, if it be required, excite the respiration by speaking to the patient or by irritating the skin. (*c*) If the state of the respiration become alarming, the inhalation of chloroform should be discontinued at once, and the operation be performed without delay. Extreme asphyxia and prostration from diphtheritic poisoning are regarded as absolute contra-indications. Marked cyanosis without, and slight cyanosis with impeded expiration are both regarded as contra-indications, though not so stringent as the conditions previously mentioned. Slight cyanosis without obstructed expiration and a very early age are not regarded as contra-indications. In the author's opinion, if the operation be not contra-indicated by the age of the infant, neither will the inhalation of chloroform be contra-indicated.—*Révue de Chirurgie.*

Chylothorax.—A case of this kind is reported by Dr. Neuenkirchen. Very few cases of chylothorax are on record, but all those hitherto observed have tended to prove that the disease is generally brought about by direct injury, and that the condition is rapidly fatal in its results. Chylous ascites is more common, and is generally produced by pressure upon some part of the thoracic duct causing rupture of it or some afferent lymphatic vessel which has become dilated. In the case recorded, that of a single lady, aged forty-five, the patient's previous history threw no light upon the causation of the disease, and the only symptom produced was that of dyspnœa, at first only on exertion, but afterward continuous when in absolute rest. This appeared in 1884, and fluid, described as milky, was at that time removed from the left pleura to the amount of about a litre, giving complete relief to the dyspnœa. The patient remained free from dyspnœa, or any other trouble, till December, 1888, when the breathing again became embarrassed, but no other symptoms showed themselves until six months later, when gradual loss of strength was complained of, and slight œdema of the feet was noticed. It was then found that the left side of the chest was nearly normal as regards its physical signs, but that fluid had collected in the right pleura. With this exception the most searching clinical examina-

tion failed to show any other abnormality. The right pleura was tapped with an ordinary trochar and siphon tube, and the lung expanded as the fluid was withdrawn; some degree of pain and collapse being caused, which soon subsided under stimulants. The fluid, as before, had a milky appearance, and, on standing, became covered with a layer of creamy consistence. Microscopically it consisted of molecular granules, scattered round cells, and a few blood-corpuscles, but no actual fat-cells. By chemical examination it was found to be alkaline, specific gravity 1.017, and to contain water, traces of casein, albumin, fat, sugar of milk, and salts. The exact quantitative proportions of each are given in detail. The patient was tapped several times, until it was found that reaccumulation seemed to be aided by the frequent tapping, and it was thought that the reduction of pressure within the pleura might be having the effect of drawing out the chylous fluid from its natural channels. It was therefore left to itself. The patient in the meantime is enjoying good health, the only new feature in the case being cessation of menses, which has been present since the first tapping in 1889.—*St. Petersburger Medicinische Wochenschrift.*

Personal Nomenclature of Disease.—Addison's Disease.—Disease of supra-renal capsules, with bronzing of skin.
Albert's Disease.—Fungous mycosis.
Aran-Duchêne's Disease.—Progressive muscle atrophy.
Astley Cooper's Hernia.—Crural hernia with multiple sac.
Argyll-Robertson's Symptom.—Absence of phosphenes.
Basedow's Disease.—Exophthalmic goitre.
Bazin's Disease.—Buccal psoriasis.
Bèchard's Disease.—Hernia passing through the saphenous orifice.
Bell's Paralysis.—Paralysis of the seventh pair.
Baudin's Law.—Antagonism of tuberculosis and impaludism.
Boyer's Cyst.—Subhyoid cyst.
Bright's Disease.—Albuminous nephritis.
Brown-Séquard's Syndroma. — Hemiparaplegia, with hemianæsthesia on the opposite side.
Cazenave's Lupus.—Erythematous lupus.
Charcot's Disease.—Arthropathy of the ataxic, and amyotrophic lateral sclerosis.
Cheyne-Stokes' Respiration.—Uræmic respiration.
Cloquet's Hernia.—Perineal hernia.
Colles' Law.—Non-infection of a mother by a syphilitic son.
Corrigan's Disease.—Aortic insufficiency.
Corvisart's Expression.—Asystolic expression of face.
Cruveilhier's Disease.—Simple ulcer of the stomach.
Donders' Glaucoma.—Simple atrophic glaucoma.
Dressler's Disease. Paroxysmal hæmoglobinuria.
Dubini's Disease.—Electrical chorea.
Duchenne's Disease.—Locomotor ataxy.
Duchenne's Paralysis.—Pseudo-hypertrophic paralysis.
Duhring's Disease.—Herpetiform dermatitis.
Dupuytren's Hydrocele.—Hydrocele with double sac.
Dupuytren's Disease.—Contraction of the palmar aponeurosis.
Erasmus Wilson's Disease.—General exfoliating dermatitis.
Eichstedt's Disease.—Pityriasis versicolor.
Erb's Disease.—Paralysis of the brachial plexus.
Erb-Charcot's Disease.—Spasmodic tabes dorsalis.
Fouchard's Disease.—Alveolo dental periostitis.
Friedereich's Disease.—Hereditary locomotor ataxy.
Gerier's Disease.—Paralytic vertigo.
Gibert's Pityriasis.—Pityriasis rosacea.
Gibbon's Hydrocele.—Hydrocele coexisting with hernia.
G. de la Tourette's Disease.—Motor incoördination.
Goyraud's Hernia.—Interstitial inguinal hernia.
Graves's Disease.—Exophthalmic goitre.
De Graefe's Sign.—Disassociation of the movements of the eyeball and the upper eyelid.
Guyon's Sign.—Ballottement of the kidney.
Harley's Disease.—Paroxysmal hæmoglobinuria.
Heberden's Rheumatism.—Rheumatism of the small joints with nodes.
Hebra's Disease.—Polymorphous erythema.
Hebra's Pityriasis.—Chronic red pityriasis.
Hebra's Prurigo.—True idiopathic purpura.
Henoch's Purpura.—Prurigo with abdominal symptoms.
Heselbach's Hernia.—Crural hernia with multiple sac.
Hippocrates's Expression.—The expression on the face of the dying.
Hodgkin's Disease.—Adenitis.
Hodgson's Disease.—Atheroma of the aorta.
Huguier's Disease.—Uterine fibro-myoma.
Hutchinson's Tooth.—Syphilitic tooth, semilunar notch of the edge.
Hutchinson's Triad.—Dental notching, interstitial keratitis, otitis (hereditary syphilis).
Jacob's Ulcer.—Cancroid ulcer.
Jacksonian Epilepsy.—Partial epilepsy.
Kaposi's Disease.—Xeroderma pigmentosa.
Kopp's Asthma.—Thymic asthma, spasm of the glottis.
Kronlein's Hernia.—Pro-peritoneal inguinal hernia.
Laennec's Cirrhosis.—Atrophic cirrhosis.
Landry's Disease.—Acute ascending paralysis.
Laugier's Hernia.—Hernia across Gimbernat's ligament.
Leber's Disease.—Inherited optic atrophy.
Levert's Law.—Marginal insertion of the cord in a short placenta.
Littre's Hernia.—Diverticular hernia.
Ludwig's Angina.—Infectious subhyoid phlegmon.
Malassez's Disease.—Cyst of the testicle.
Ménière's Disease.—Labyrinthine vertigo.
Millar's Asthma.—Stridulous laryngitis, spasm of glottis.
Morrand's Foot.—Foot with eight toes.
Morvan's Disease.—Analgesic paralysis of the extremities.
Paget's Disease.—Precancerous eczema of the nipple.
Paget's Disease.—Hypertrophic osteitis deformans.
Parrot's Disease.—Syphilitic pseudo-paralysis.
Parkinson's Disease.—Paralysis agitans.
Parry's Disease.—Exophthalmic goitre.
Pavy's Disease.—Intermittent albuminuria.
Petit's Hernia.—Lumbar hernia.
Pott's Aneurism.—Aneurism by anastomosis.
Pott's Fracture.—Fracture of the fibula, with dislocation of the ankle-joint.
Pott's Disease.—Vertebral osteitis.
Raynaud's Disease.—Symmetrical gangrene of the extremities.
Reclus's Disease.—Cystic disease of the mamma.
Richter's Hernia.—Parietal enterocele.
Rivolta's Disease.—Actinomycosis.
Romberg's Symptom.—Unsteadiness of gait of persons suffering from ataxy in the dark.
Rosenbach's Symptom.—Absence of abdominal reflex.
Salaam's Tic.—Convulsive salutation.
Soemich's Ulcer.—Infectious ulcer of the cornea.
Storck's Blennorrhœa.—Blennorrhœa of the respiratory passages.
Stokes's Law.—Paralysis of the subjacent muscles in inflammation of serous and mucous membranes.
Sydenham's Chorea.—Common chorea.
Thomson's Disease.—Muscular spasm at the commencement of voluntary movement.
Tornwald's Disease.—Inflammation of the pharyngeal gland of Luschka.
Velpeau's Hernia.—Crural hernia in front of the vessels.
Volkman's Deformity.—Congenital dislocation of the tibio-tarsal articulation.
Wardrop's Disease.—Malignant onychia.
Weil's Disease.—Abortive typhus with jaundice.
Werlhoff's Disease.—Hæmorrhagic purpura.
Westphal's Symptom.—Absence of knee reflex.
Willad's Lupus.—Tubercular lupus.
Winckel's Disease.—Cyanosis of newly born children.—*Journal de Médecine de Paris.*

MEDICAL RECORD:

New York, March 14, 1891.

THE INFLUENCE OF TEMPERATURE UPON MORTALITY.

IT is well known that there is a fixed and definite relation between climate and disease, certain diseases being peculiar to certain climates. Thus in the colder regions we find most prevalent the diseases of the respiratory tract and kidneys, together with certain fevers, while in warm climes we note diseases of the digestive organs in addition to certain specific fevers distinct from those met with in the northern portions of the earth's surface. In the so-called temperate regions, where it is very hot for a portion of the year and very cold for another portion, we find diseases of both the kinds above mentioned, summer being marked by the prevalence of many of the diseases peculiar to the tropics, while in winter the diseases of the north prevail.

It is natural to conclude from the fact that diseases are grouped in this manner that one of the chief causes of their prevalence must be looked for in the thermal conditions of the different zones and of the different seasons in any particular zone. This has been shown graphically by Dr. A. Magelssen, of Christiania, in a recent work entitled "The Dependence of Disease upon the Weather."[1] In a series of charts depicting the temperature curve for different seasons in different countries, he shows that the death-rate for the respective regions rises and falls in direct relation to the temperature. Thus in northern countries, in the Scandinavian Peninsula for example, the mortality is greatest in the coldest part of the year, for the reason that respiratory diseases, to which the majority of deaths in these countries are due, are most frequent at this time, while in summer the death-rate is at its lowest, digestive diseases being comparatively uncommon there. In southern countries, on the other hand, the greatest mortality is from disorders of the digestive organs and from the fevers peculiar to tropical climes, consequently the death-rate reaches its highest point during the summer season. In southern regions the mortality curve coincides with that of the temperature, while in the north it rises and falls inversely to that of the temperature.

It is not only diseases of the digestive and respiratory organs, however, that are thus shown to be affected by the atmospheric changes, but the infectious diseases peculiar to northern and southern climates respectively appear to be influenced in like manner. Thus in the north the mortality from infectious diseases is greatest in winter, while in the south the opposite prevails, infectious diseases being both more frequent and more fatal during the hot season of the year.

As a result of his observations and studies, Dr. Magelsseu concludes that the real basis for the fluctuations of mortality in cold as well as in hot countries is to be found in the temperature changes. Under the influence of a higher or a lower temperature are developed in the inhabitants of the different regions the conditions favoring a greater or a less susceptibility to the action of the specific germs of disease.

[1] Om Sygdommenes Afhængighed af Veirliget. Med 10 lithograverede Tavler. Af A. Magelssen, Læge. Christiania, 1889.

THE DWINDLING POPULATION OF FRANCE.

FOR many years the public men of France have been concerned over the fact that their country is becoming gradually depopulated, and numerous are the means which have been proposed to ward off the evil. It has generally been assumed that the cause of the trouble lay in the growing custom of artificially preventing conception, so as to avoid the inconvenience and expense of a large family, and everything possible has been done to arrest the growth of this evil; among other things substantial money prizes having been offered to families of seven or more children.

This, however, according to a recent writer on the subject, is not the real cause of the decreasing population, which he says is to be found not so much in a lowered birth-rate as it is in an increased mortality. The fertility of the French has always, at least for many years past, compared unfavorably with that of other nations, the Germans, for example; but in spite of this, statistics, it is claimed, show that the population would not decrease were it not for the comparatively high death-rate from small-pox and typhoid fever. Brouardel states that variola kills annually, in France, 14,000 persons, as against 110 in Germany, nearly all the victims being under forty years of age; and typhoid fever is responsible for about 23,000 deaths annually, those dying being aged, mostly, from fifteen to twenty-five years.

The remedies indicated, if these statements are correct, would be compulsory vaccination and revaccination, and the interdiction of the use of polluted water. The Academy of Medicine has accepted this opinion, and by a vote adopted it as its own. Whatever share these diseases may have in reducing the population of France, it remains true, nevertheless, that the birth-rate in that country is steadily diminishing.

A NEW OPERATION FOR OLD TRAUMATIC DISLOCATIONS OF THE HIP.

AT a recent meeting of the Surgical Society of Paris, M. Nélaton described an operation which he had performed in a case of old traumatic dislocation of the hip, and which had given great relief to the patient. The dislocation was into the sciatic notch, and was eight months old, and all attempts made to reduce it in the usual way had failed utterly. Believing that failure to reduce by the

ordinary manœuvres was due to shortening of the gluteal and adductor muscles, as well as to the interposition of the anterior portion of the torn capsule between the head of the femur and the cotyloid cavity, which had become obliterated, M. Nélaton proceeded to operate in the following manner. He exposed and liberated on all sides the head of the femur by an incision made over its seat, removing with the bone forceps its spherical portion at the level of the neck. He then flexed the limb and detached the capsule from its posterior insertion, thus allowing its anterior portion to be cleared from the cotyloid cavity. The latter was now enlarged by a further clearing process to its normal depth and dimensions, and in this reconstituted cavity was placed the resected end of the femur. The tendency to subsequent shortening was nullified, the speaker believed, by the fact that, owing to the shortening of the bone by an inch and a half, the gluteal and adductor muscles acted at a disadvantage. The retention of the femur in its normal position was also aided materially by the scooping out of the cotyloid cavity. The after treatment of this case consisted in judiciously conducted movements of traction and flexion, and the result of the operation surpassed the surgeon's expectations.

M. Nélaton claimed, we believe, that this was the first time this operation had been done for the relief of traumatic dislocation of the hip; but it cannot strictly be called a new operation in any event, for it was practised some time ago by Heussner in a case of congenital dislocation, and has been recommended, if not executed, by other orthopedic surgeons for similar cases to the one of the German surgeon.

THE MANAGEMENT OF SYMPATHETIC OPHTHALMIA.

At a meeting of the Académie de Médecine in November last, M. Abadie professed to have discovered a mode of treatment in sympathetic ophthalmia which would render unnecessary the enucleation of the injured eye. His plan was to cauterize, by means of the galvano-cautery, the edges of the wound in the injured eye, and then inject into its substance a drop of a one per mil solution of perchloride of mercury. This caused the subsidence of all sympathetic morbid phenomena. Should a single injection not suffice, it might be repeated in a few days, but it was seldom necessary, he claimed, to give more than two or three injections in order to bring about a complete cure of any case, even those apparently the most grave.

The Acid of Butter has been thought to be mainly palmitic; but Mr. J. A. Wanklyn (*The Lancet*) asserts that this is not so. He has just discovered that the real acid is a different and peculiar one. It has the curious property of consolidating or gelatinizing alcohol. At temperatures below 5° C. it gelatinizes more than five times its weight of alcohol. Part of the alcohol is held mechanically by a sponge-like action, and part is retained in chemical combination. Palmitic acid possesses no such property; indeed, no other substance resembles the new acid in this particular.

News of the Week.

One Doctor Shoots Another.—Dr. George Baird, of Wheeling, W. Va., a member of the City Water Board and one of the most prominent physicians of the city, was shot and almost instantly killed March 7th, by Dr. George I. Garrison, ex-City Health Officer and a physician of high standing. Trouble between the two physicians dates back for a year. Before that time they were the closest friends, and when Dr. Garrison was chosen Health Officer, he being then a young physician, Dr. Baird performed the duties of the office while Dr. Garrison was absent at the college, and allowed the latter to draw the salary. About a year ago Dr. Garrison obtained a warrant for the arrest of Dr. Baird, charging him with a violation of law as to a death certificate, and this led up to a personal encounter.

Koch's Lymph at the Good Samaritan Hospital in Cincinnati.—S. P. Kramer, M.D., writes: "Experiments with the Koch fluid were begun January 14th. Nineteen cases were under observation. The usual reactions and attendant symptoms were observed. The report says, in reference to six cases of incipient pulmonary phthisis, that they were all improved. In one case the previously existing physical signs of infiltration 'had nearly disappeared.' The patient had gained five pounds, and left the hospital without cough and expectoration." Dr. Kramer maintains "that the remedy is a specific against tuberculosis, no one who has seen its action in a case of lupus will doubt. In so far as regards the science of medicine, the specific character of the remedy may be considered a settled fact. The cure of one case of lupus is sufficient evidence for this. Everything else, the determination of suitable cases, surgical aid, prevention of accidents, are details to be settled by the physician's art. Nor is this to be done in a day. We have but to remember our experience with mercury and iodine as specifics in lues. These remedies have been known to medicine for centuries, but it is only within the present generation that we have learned the proper use of them. Perhaps the benefit of Koch's remedy will be scarcely felt by the present generation."

The Alumni Association of Charity Hospital, New York, held its first anniversary dinner on the evening of March 10th at Clark's. Dr. D. Bryson Delavan, the president, was the efficient and tasteful toastmaster. Speeches were made by Drs E. L. Keyes, R. Guitteras (vice president), W. M. Polk, L. B. Bangs, Chas. Phelps, H. S. Norris, Clement Cleveland, Nelson H. Henry, H. M. Biggs, T. H. Allen, R. W. Taylor, and Geo F. Shrady.

A "Bill for an Act to Establish a State Board of Health and to Regulate the Practice of Medicine in the State of Nebraska, etc.," has been introduced into the Legislature.

Surgeon-General of Florida.—Dr. Henry Bacon, of Jacksonville, Florida, formerly an interne of Charity Hospital, Blackwell's Island, has been appointed by Governor Fleming, Surgeon-General of the State of Florida.

There are at present only eleven physicians who have discovered a better kind of inoculating fluid than that of Dr. Koch.

A Suit for Fees as a Medical Expert.—In a recent case in this State a physician brought suit to recover for his services as a medical expert on the contest of a will. He was the only witness on his own behalf, and produced letters and telegrams showing employment. These letters were, however, from lawyers acting not only for the defendant but for other persons, and, on the denial that they were acting for the person sued, the court decided against the physician. This judgment was appealed from, but has now been affirmed. The weight of evidence seemed to be against the physician, and the Appellate Court refused to disturb the verdict.

Dr. G. W. Broome succeeds Dr. Bransford Lewis in the editorship of the *Weekly Medical Review*.

Spain Rejects the Lymph.—A commission of six medical men, appointed to investigate the Koch method of treating consumptives, has reported in favor of the total suspension of that form of treatment, it haying been found, according to the committee's report, that not a single cure had been effected here by the use of the method.

Treatment of Phthisis by Transfusion.—A cablegram announces that four deaths have occurred within five days as a result of the transfusion of blood according to the method of Dr. Bernheim, and that the Bernheim treatment is more dangerous than treatment by the Koch method. Dr. Bernheim, however, maintains that he has had success in eighty cases of tuberculosis.

The Discoveries of Pasteur and Koch render necessary the coining of some new words. One of these is the adjective "immune," a good word and a useful one. We need, however, still more, a corresponding verb signifying "to make immune," and we note that "immunising" has already been adopted by some writers. This is rather clumsy. To "immunate" would correspond better with the allied terms "vaccine" and vaccinate.

The Late Dr. George R. Cutter. — The following resolution was passed by the Board of Surgeons and afterward by the Board of Directors of the New York Eye and Ear Infirmary at their last regular meeting: "In view of the death of Dr. George Rogers Cutter, which occurred on February 12th, after a brief illness, the Board of Surgeons of the New York Eye and Ear Infirmary hereby place on record their warm sense of his estimable qualities as a man and as a Physician. Beginning his connection with the institution as Resident Surgeon he was afterward placed upon the Staff and acquired the position of Surgeon in 1877. His career in the service of the institution covers a period of twenty-one years. He was noteworthy for fidelity, promptness, and zeal in his work. His industry was unflagging. Quick in thought and action, he was prompt to recognize the value of new methods and to profit by his own observation and experience. He was a scholarly man and never tired of acquainting himself with the most recent literature of his profession. Gifted in the art of acquiring languages, his reading was wide and his discernment good. The Surgeons feel that they have lost a wise, gifted, and true man, an esteemed colleague and an able surgeon. While they express their own regret they beg to tender their sincere condolence and sympathy to his wife and family."

Dr. M. H. Kerwin, the first physician in the Northwest to visit Berlin to secure and administer the Koch lymph, died at Milwaukee suddenly last week of peritonitis He was thirty-five years of age.

The Preaching and Practice of Orthoepy—Most persons in this country pronounce phthisis "tee-sis;" yet among eight lexicographical authorities quoted by Webster not one gives this pronunciation, the predominant one being "thi-sis." Only one authority (Smart) calls it "tisis," a pronunciation prevalent in Boston. Our esteemed leguminophagous colleagues cannot, therefore, put on any airs, other than those legitimately resulting from their strong east winds.

Recent Statistics of American Medical Colleges.—According to the last report of the Illinois State Board of Health, there are now 148 medical colleges of all kinds in the United States and Canada, there being 135 in this country and 13 in Canada, and of these, 129 require certain educational qualifications for matriculation. In 1882, such preliminary knowledge was required by only 22 colleges. The number of colleges that to day require attendance on three or more courses of lectures is 85, as compared with 22 that made such requirements in 1882. During the term from 1882 to 1891, the average duration of the lecture term has increased from an average of 23.5 weeks to 26.3 weeks. In 1882–83 there were 8 colleges that held terms of but sixteen weeks. The number that give such limited instruction at the present time is not given, but the number of colleges whose term is six months or more is 111.

College Commencements.—The University of Tennessee held its sixteenth annual commencement on February 24th, and graduated a class of one hundred and twenty-three doctors and dentists. May the former fill few and the latter many cavities!

A Suit for Malpractice Decided Against the Surgeon.—A case occurred recently in the Supreme Court at Syracuse which has excited much interest in medical circles. The accounts say that an action was brought by J. H. Link, as guardian, against Dr. J. W. Sheldon, for malpractice, laying damages at $10,000. It was alleged that Dr. Sheldon made a botch of reducing a fracture of the wrist of Mr. Link's son. Dr. Sheldon is a homœopathic physician of standing. The prosecution called numerous regular physicians to prove malpractice, and the case finally assumed the phase of a fight between the two schools. A great deal of expert testimony was given by prominent physicians. The taking of testimony lasted nearly all of the week. The court room was crowded, and sides were taken as much by the spectators as by the numerous physicians. The case was given to the jury this afternoon, and they returned a verdict for $4,000.

Dr. W. C. McFarland, of this city, died on Saturday, February 28th. He was a graduate of the College of Physicians and Surgeons, Class of 1867.

We note the announcement that Dr. Luther B. Grandy has been made one of the editorial staff of the *Atlanta Medical and Surgical Journal*, and we are further pleased to learn that Dr. Grandy is "one of the brainiest young men in the profession." We welcome Dr. Grandy to the ranks of journalism and are prepared to feel proud of his brain.

Social Evil Act.—The Legislature of Missouri has listened to the second reading of an act for the regulation of prostitution.

The Chicago Medical College is to have a new building costing $100,000.

The State Board of Health of Maine has introduced a bill into the Legislature to provide for the registration of vital statistics. The bill was prepared by the State Board of Health after an extended examination of the existing laws of other States, and an effort is now being made to secure its passage.

Medical Legislation in Missouri.—There is now pending in the Missouri Legislature a bill to compel all medical colleges in the State to adopt three courses of lectures as a condition for graduation. All of the medical colleges in the State, excepting one, are favorable to the bill.

The Illinois State Board of Health has decided that hereafter it will recognize no foreign diploma that does not confer upon its holder the right to practise medicine in the country in which it was granted.

Is the State Responsible for Lightning Strokes?—A bill has recently been introduced in the Massachusetts House of Representatives appropriating $300 to a man who was struck by lightning, as he was at work on the State camp-ground when struck. It seems that the State considers itself responsible for the accident.

Preliminary Programme of the Second Triennial Congress of American Physicians and Surgeons.—Tuesday, September 22d, 3 P.M. Discussion on "Conditions Underlying the Infection of Wounds, Including a Discussion of Disinfection with Reference to Treatment of Wounds; of the Relation of Bacteria to Suppuration; of the Resistance of Tissues to the Multiplication of Bacteria, and of the Effects of Antiseptic Agents on Wounds." *Referee*, Dr. William H. Welch, of Baltimore, Md.; *Co-Referee*, Dr. Roswell Park, of Buffalo, N. Y. The discussion will be adjourned if necessary until Friday afternoon. Wednesday, September 23d, 3 P.M. Discussion on "The Late Manifestations of Syphilis." *Referee*, Dr. Phineas S. Conner, of Cincinnati, O.; *Co Referee*, Dr. Abner Post, of Boston, Mass. At 8 P.M. The President's Address, to be followed by a reception. Thursday, September 24th, 3 P.M. Discussion on "Fibroid Processes (Chronic Interstitial Inflammation, Scleroses); Their Pathology and Etiology, with Special Reference to the Influence of Diathesis and Heredity." *Referee*, Dr. Alfred L. Loomis, of New York City; *Co-Referee*, Dr. William Osler, of Baltimore, Md. Friday, September 25th, 3 P.M. If necessary the discussion on the "Conditions Underlying the Infection of Wounds," etc., will be resumed.

Legislation to Reduce Doctor's Fees.—A bill has been introduced by a delegate to the House of Representatives of Missouri, to limit physicians' fees to the uniform rate of fifty cents for an office consultation, and one dollar for a visit. This is a most absurd proposition. We do not know whether the introducer of the bill is a lawyer, or a butcher, or a barber, but he might just as well, while he is about it, introduce a bill regulating the price of beef, of counsel fees, or of a shave.

A Bill to Regulate the Practice of Medicine in Michigan has been introduced into the Legislature. It appears to have been carefully drawn; it has the support of the State Society and apparently deserves to be made a law.

A Bill to Regulate the Practice of Medicine in Pennsylvania has been introduced into the Legislature and there seems to be some possibility of its passing. It provides for a Licensing Board composed of ten regulars, ten homœopaths, and ten eclectics. It is a most unjust and absurd scheme.

The Legislature of Wisconsin has before it a medical practice act, an act to establish a State School for idiots, and a bill merging the State Boards controlling the State and county insane asylums into one.

State Board of Medical Examiners.—In accordance with chapter 507 of the Laws of 1890 the Regents have appointed State Boards of Medical Examiners as follows: From the Medical Society of the State of New York: for three years from September 1, 1891, W. W. Potter, of Buffalo, William S. Ely, of Rochester, and Maurice J. Levi, of Albany; for two years from September 1, 1891, William C. Way, of Elmira, and George R. Fowler, of Brooklyn; for one year from September 1, 1891, J. P. Creveling, of Auburn, and Eugene Beach, of Gloversville. From the Homœopathic Medical Society of the State of New York: for three years from September 1, 1891, William S. Searle, of Brooklyn, Horace M. Paine, of Albany, and Asa S. Gosh, of Fredonia; for two years from September 1, 1891, John McE. Wetmore, of New York, and Jay W. Sheldon, of Syracuse; for one year from September 1, 1891, E. E. Snyder, of Binghamton, and A. R. Wright, of Buffalo.

Reviews and Notices of Books.

URINARY DISORDERS CONNECTED WITH THE BLADDER, PROSTATE, AND URETHRA. Lectures delivered at St. Peter's (in 1890) by REGINALD HARRISON, F.R.C.S. Surgeon to St. Peter's Hospital; Hunterian Professor of Pathology and Surgery at the Royal College of Surgeons of England, etc. Pp. 81. London: Baillière, Tindall & Cox.

DR. HARRISON is a master of his subject and through the British medical press has given much of value to the literature of medicine. His work is especially valuable because the well-trodden paths of knowledge are departed from for new and original ones. His new work on urinary disorders is no exception to the rule and the lectures on prostatic obstruction, hæmaturia, gleet, and the therapeutics of the bladder bristle with new points of practical usefulness.

A TREATISE ON THE DISEASES OF INFANCY AND CHILDHOOD. By J. LEWIS SMITH, M.D., Clinical Professor of Diseases of Children in Bellevue Hospital Medical College, New York, etc. Seventh edition, thoroughly revised. In one octavo volume of 881 pages, with 51 Illustrations. Philadelphia: Lea Brothers & Co. 1890.

THE new edition of Dr. Smith's well-known work on diseases of children compares favorably with other textbooks on the same subject. By the incorporation of the results of recent researches much new matter has been added to the volume. A special chapter on "Intubation," from the pen of Dr. O'Dwyer, finds suitable place in this volume. In its present shape the work will be appreciated by all those whose practice includes treatment of the numerous ailments of children.

WOOD'S MEDICAL AND SURGICAL MONOGRAPHS. Volume 8, Number 3. December, 1890. Contents: "Practical Guide to the Demonstration of Bacteria in Animal Tissues," by DR. H. KÜHNE, Wiesbaden; "On the Present Position of Antiseptic Surgery," by SIR JOSEPH LISTER, F.R.S.; "Cancer and Its Complications," by CHARLES EGERTON JENNINGS; "The Treatment of Epilepsy," by DR. CH. FÉRÉ; "Handbook of Dr. Koch's Treatment in Tubercular Disease," by DRS. EDWARD F. GRÜN and WALTER D. SEVERN. Pp. 308. Illustrated. Published monthly. $10 per year, single copies, $1. New York: William Wood & Co., 56 & 58 Lafayette Place.

THE wants of the profession are studied and supplied by "Wood's Monographs." They are always "up to the times." This is well illustrated by the December number, which contains among its five most excellent papers a handbook of Professor Koch's treatment of tubercular disease. What could be more opportune or more welcome? It is the first and probably the only treatise of the kind yet printed. The authors had *carte blanche* in the Berlin hospitals, and they present everything known about the new discovery in a clear, concise manner, and so plainly that any capable physician having the lymph could carry out the treatment. It is probably only a matter of a short time till the lymph will be in the hands of the general practitioner, and hence the work under review is invaluable. Dr. Kühne's paper on the demonstration of the tubercle bacillus in animal tissues will be especially welcome, because it goes into minute detail and gives methods that every doctor can carry out. Most essays on the subject presuppose entirely too much knowledge and skill in the reader. Dr. Joseph Lister's article on antisepsis will be read with interest. It leans decidedly toward asepsis. Exceedingly weak solutions are advocated, on the ground that they answer every purpose and require less drainage. Drainage-tubes, which can hardly be made aseptic, and which invariably leave sinuses behind are one of the blots on modern surgery. The remaining articles of the book, "Cancer and Its Complications," and "The Treatment of Epilepsy," are worthy of their distinguished authors, complete, scholarly, entertaining, and instructive. All in all the December Monograph is a most valuable addition to medical literature.

TRANSACTIONS OF THE AMERICAN ORTHOPEDIC ASSOCIATION. Vol. III. Philadelphia: Published by the Association. 1890.

THIS is a report of the proceedings of the fourth session of the Association, which was held in Philadelphia, Pa., on September 16, 17, and 18, 1890. An abstract of most of the papers here published in full appeared in these columns in October last in our special report of the meeting of the Association. Most of the papers show evidence of careful preparation by the authors, and together they form a valuable addition to the literature of orthopedic surgery. The volume is well printed and neatly bound, and the illustrations are above the average.

WOOD'S MEDICAL AND SURGICAL MONOGRAPHS FOR JANUARY. Contents: "Advances in Bacteriology," by R. KOCH, M.D.; "Formulary of New Remedies and New Medicinal Preparations," by H. BOCQUILLON-LIMOUSIN; "Anæsthetics, A Discussion," by DR. WILLIAM MACEWEN and others. Pp. 263. Price, per year, $10, single copies, $1. New York: William Wood & Co.

THE January number of Wood's popular series of monographs is unusually interesting and valuable. The great French chemist, Limousin, contributes a formulary of new remedies that is in itself worth many times the price of the book. About three hundred of the latest acquisitions to the materia medica are fully described, their therapeutical properties, uses, methods of preparation and dispensing, and doses being given. The discussion on anæsthetics is in touch with the times and the names of the authors. Drs. William Macewen, Joseph Coats, T. Brown Henderson, Robert Kirk, and Hartley of Leeds are sufficient vouchers for the excellence of the discussion. The third article is the one by Professor Koch, it being his famous paper read before the recent Berlin Congress, in which he gave the first news of his discovery of the curative lymph. The article is a comprehensive review of the progress in and present status of bacteriology.

TRANSACTIONS OF THE MEDICAL ASSOCIATION OF GEORGIA. Forty-first Annual Session. 1890. Pp. 222. Macon, Ga.: J. W. Burke & Co.

TEN papers by the leading physicians and surgeons of Georgia are contained in this very handsomely bound volume. "Aseptic *vs.* Antiseptic Surgery," "One Hundred and Seventy Cases of Railroad Surgery," "The Importance of Examination of Urine," and "The Female Urethra," are especially worthy of note.

THE WORK-HOUSE AND ITS MEDICAL OFFICER. By DR. ALFRED SHEEN, Senior Surgeon, Glamorgan and Monmouthshire Infirmary, Cardiff; Surgeon, Cardiff Workhouse and Hospital. Pp. 80. Bristol: John Wright & Co.

THIS is the second edition of a little work that gained great popularity in England. It details the proper management of a public institution, and is written by one who is authority on the subject. The medical officers of any institution can profit by a study of this useful book.

HEPATITIS AND HEPATIC ABSCESS: Their Etiology, Diagnosis, and Treatment. By G. HARRISON YOUNGE, Surgeon, English Army Medical Staff. Pp. 43. London: T. W. Danks & Co.

DR. YOUNGE has had unusual facilities for the study of liver disease during a long residence in India. His views as to etiology and treatment are original, tenable, and worthy of consideration.

ACCOUNT OF THE LIFE AND WORKS OF MAISTER PETER LOWE, THE FOUNDER OF THE FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW. By JAMES FINLAYSON, M.D. Pp. 83. Illustrated. Glasgow: James Maclehose & Sons.

NO handsomer piece of typographical art ever issued from the medical press. It is printed on heavy linen, edges uncut, beautifully illustrated with a photogravure portrait and a number of photo-lithographs, and enclosed in heavy paper lids covered with parchment printed in two colors. The reading matter is worthy of such fine dressing, for it is unique and valuable. The title indicates its character.

HAND-BOOK OF MATERIA MEDICA, PHARMACY, AND THERAPEUTICS, including the Physiological Action of Drugs, the Special Therapeutics of Disease, Official and Extemporaneous Pharmacy, and Minute Directions for Prescription Writing. By SAMUEL O. L. POTTER, A.M., M.D. Second edition. Revised and enlarged. 766 pp. Philadelphia: P. Blakiston, Son & Co. 1890.

THE present volume differs from other well-known works on Materia Medica in several respects. It is far less complete than some of them, but it embodies in concise form the more essential elements of practical therapy, so far as related to the use of drugs. The subject-matter is very conveniently arranged in alphabetical order. Part III. is a feature of the book, being devoted to special therapeutics. Under the heading of the principal diseases, alphabetically considered, the practitioner will find a brief reference to the drugs most commonly employed in their treatment, together with the particular indications governing their choice.

Altogether Dr. Potter's treatise will be found useful as a work of reference, especially by that large class of physicians who lack the time to look through the more bulky manuals.

Society Reports.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 19, 1891.

ALFRED L. LOOMIS, M.D., PRESIDENT IN THE CHAIR.

Operative Surgical Treatment for Aneurism of the First Two Portions of the Subclavian Artery.— DR. JOSEPH D. BRYANT read the paper (see p. 305).

Prefers Treatment by Pressure. — DR. JOHN A. WYETH thought the most enthusiastic operative surgeon would admit that surgical interference with aneurism at the root of the neck, and especially, as bearing on the paper, of the first and second portions of the subclavian artery was bloody and fatal in the extreme. As the reader of the paper had shown, every case but one of deligation of the innominate had ended fatally as a direct result of the operation. The single exception occurred in the preaseptic days.

All cases in which the first portion of the subclavian had been tied had died, all but one of hemorrhage. He also mentioned the fact that aneurism of the subclavian almost invariably occurred upon the right side. With such results from proximal ligature, he turned to distal ligature, but here found the results almost equally unsatisfactory, almost as fatal. Statistics were here given. With such a picture before him he would resort to surgical interference only as a last measure. The difference in the sum of life between operative and non-operative interference had been forty-seven years in favor of the latter.

By non-operative interference he meant pressure, which had been advocated by Mr. Holmes. The pressure was made by means of a ball upon the tumor at the root of the neck. Five cases were on record treated in this manner, of which four were cured, one died. To this number Dr. Wyeth could add two more, one treated by himself, the other seen by him and treated by Dr. James P. Tuttle. He employed in his case a rubber ball of the kind children played with, forming an elastic cup over the tumor when pressure was exerted. The patient was kept at rest in dorsal decubitus, and was discharged, cured, at the end of two months. Dr. Tuttle's case was also cured, it now being twelve months since treatment had been discontinued. He therefore thought that in all cases in which the aneurismal tumor projected above the clavicle one should try pressure in preference to operative interference.

Objections to Pressure Treatment.—DR. L. A. STIMSON referred to the difficulty of distinguishing between aneurism of the first and second portions of the subclavian and other aneurismal tumors in the neck. If the aorta were involved, pressure could not effect a cure, and even in cases strictly within discussion he thought the results of pressure treatment would perhaps be less favorable in the future than in the past. He thought the results of distal ligature for aneurism of the innominate, and therefore of the subclavian, were not so bad. He had had one case live twenty-one months, then death took place from phthisis. The aneurism was found completely filled with a firm laminated clot. As to MacEwen's method of introducing a needle and scratching the wall of the aneurism, he would be a little afraid of it. Doubtless the action was considerably like that of introducing a number of pins or needles, a method by which some surgeons had claimed very good results.

Diagnosis and Medical Treatment.—DR. E. G. JANEWAY sent a letter briefly discussing this subject. He said it was rare for him to be called upon to make a diagnosis of aneurism of the first and second portions of the subclavian. The diseases which it had simulated had been, as far as his experience had gone, aneurism of the innominate, tumor, especially lympho-sarcoma or goitre. The rule that a double murmur meant of necessity aneurism had some limitation, as he had recognized double murmur connected with goitre.

As to treatment, it usually fell to the surgeon. The success of medical treatment of any aneurism was not very great. Rest, a modified diet, medicines intended to quiet the heart's action and promote coagulation in the sac. Morphine relieved pain and quieted the heart, aconite might be useful, digitalis was liable to do harm. The continued administration of iodide of potassium in considerable doses seemed to promote coagulation in the sac. Absolute rest for months should be a part of all medical treatment. The bowels were apt, under rest and opium, to become constipated and cause straining, which should be guarded against.

Diagnosis Proximative.—DR. T. M. MARKOE thought the diagnosis of aneurism of the first and second portions of the subclavian could only be proximative, not positive. The great danger in operative treatment had been from hemorrhage, nearly always from the distal side of the ligature, due to collateral circulation. If this could be obviated it would be a long stride toward the solution of the surgical treatment. He had made all the dissections for Dr. Rogers when he tied the left subclavian about an inch and a half from its origin in the aorta for aneurism. Fatal hemorrhage took place from the distal side, the vertebral artery having evidently been the cause. He was present also at an operation where it was intended to ligate the innominate, and the operation was abandoned on account of the presence of an atheromatous patch which would have fallen within the ligature, yet in Dr. Rogers's case such a patch was present on one side of the vessel where ligated and had not interfered at all with healing and closure of the vessel on that, the proximal, side. He thought he would also tie the vertebral artery to obviate the fatal result taking place through the collateral circulation.

To Avoid Secondary Hemorrhage.—Another method which bid fair to overcome the danger of secondary hemorrhage was that of constricting the artery without entirely obliterating its canal, allowing this to take place by a process of proliferation of tissue and the formation of clot. Thus while the artery was occluded, it would not be separated so distinctly into two parts as was done by tight ligation, while objections had been offered to this method, the chief of which was that it did not make absolutely certain occlusion of the artery, yet in experiments on animals Senn had found it usually successful and in none had there been secondary hemorrhage.

DR. W. T. BULL, chairman of the Section on Surgery, under whose auspices the discussion took place, said he was in accord with the conclusions drawn by Dr. Bryant.

The discussion was closed by the author, who said that while he was aware ligation of the vertebral was not fraught with absolute danger, yet he thought it should be undertaken with greater precautions in cases like the one related.

Suture of the Bladder.—From a careful study of this subject Dr. Delefosse has arrived at the following conclusions: 1. Vesical suture should not be employed in at least two-thirds of the cases of hypogastric section, on account either of the object of the operation itself, or of the condition of the vesical walls, or of the interior of the bladder. 2. It is only absolutely indicated when there is an intra peritoneal wound of the bladder wall. When a wound of the bladder is extra-peritoneal, vesical suture should be employed when the bladder and kidneys are healthy and the urine is normal. 3. In the great majority of cases of hypogastric section, in which the use of the suture has succeeded, a partial suturing or none at all, with the employment of siphon-drainage, would give equally good results.—*Annales des Maladies Génito-urinales.*

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, January 2, 1891.

GEORGE L. PEABODY, M.D., PRESIDENT, IN THE CHAIR.

Hysteria (?) in a Man.—DR. ANDREW H. SMITH presented a patient with the following history: Isaac Nussbaum, aged thirty two, single, newsdealer, Germany. Admitted, December 3, 1890. His family history is negative. He has not had rheumatism or syphilis. He is a moderate beer drinker. His health previous to July, 1889, had been perfect. From July to October, 1889, he suffered from a severe attack of typhoid fever. On recovering from this he was troubled with attacks of dizziness and the same symptoms he now has, which have recurred at intervals since then, although he has never been entirely free from them. They are dizziness, stiffness of the left side, headache principally on the left side, ringing in the head, photophobia, pain in the back of the neck, insomnia. Three weeks ago, while undergoing severe exertion, he lost consciousness for a short time, and when he recovered the symptoms were more severe and have continued so till the present time.

Physical Examination.—He is muscular, well nourished, and not anæmic. His lungs appear normal. Breathing is rapid and shallow owing to pain on deep inspiration. Heart and other organs appear normal. There is hyperæsthesia of the entire left side—around the left nipple seems to be the point of maximum intensity. There is photophobia. His head is drawn to the right side. His patellar reflexes are both exaggerated, the left more than the right. Superficial reflexes exaggerated. Ankle clonus is present on the left side. Urine, negative. No temperature.

December 6th. This morning his entire left side became suddenly rigid and this is present still, though less marked than at first. He has buzzing and ringing noises in his head. Last night he could not pass his urine and had to be catheterized.

December 7th. Had another attack of tonic contractions of the muscles of the left side this morning. The extensor muscles were more rigid than the flexors, so that both arm and leg were strongly extended.

Ophthalmoscopic examination showed the fundus and optic disk to be normal. He has had potassium iodide, gr. xv., t.i.d., and bichloride of mercury, gr. $\frac{1}{16}$, t.i.d., since his admission. The symptoms are less marked now than they were at first, but they still persist.

THE PRESIDENT asked Dr. Smith whether he had discarded the idea of hysteria in the male.

DR. SMITH replied that he had thought of hysteria and of malingering, but the patient was willing to submit to any test. He had made no objection to the use of the Paquelin cautery. He claimed to have lost smell and taste, but these senses had not been put to any severe test, nor had they examined for limitation of the visual fields. Examination had not been made under ether. He could not say whether the muscular rigidity passed off during sleep. In fact the patient slept very little except under opiates.

DR. DANA remarked that there was no ataxia, no tremor, no inco-ordination. Being asked for a diagnosis, Dr. Dana said he would want to make a more careful examination of the patient before coming to any positive conclusion. It was his impression, however, that it was a case of tumor of the brain. He thought hysteria could be excluded by the mental condition, the hebitude and excessive pain, and the absence apparently of any of the anesthesiæ of hysteria. Hysterical paralysis was very rarely so spastic in character. He thought the diagnosis lay between tumor of the brain and, perhaps, pachymeningitis of the right side. If a tumor, it probably lay pretty deeply and well anteriorly, yet extending far enough back to involve the leg, arm, and shoulder centres, very little of the face centre. It would seem that it must lie rather deeply, because there was so little motor disturbance in the way of spasms and epileptiform attacks. He concluded by saying, however, that he would want to make a much more careful study of the patient before pronouncing on the diagnosis. Being asked by the President whether a tumor situated as he had suggested would account for the pain, Dr. Dana said it would not, and that fact threw doubt on the diagnosis.

DR. FRANCIS DELAFIELD said that, judging by what he had heard and seen of the case, he would suppose it was one of hysteria. A positive diagnosis, however, would not be justified without further observation of the patient.

A Case of Malingering.—DR. GEORGE F. SHRADY said he thought it was a case of malingering. It was sometimes very difficult to make out this condition. Dr. Smith's remark with reference to the rigidity disappearing or not during sleep reminded him of the case of a soldier in the Central Park Hospital during the war. He had assumed a bent position, which he maintained continuously four weeks. A guard was placed over him to watch him during sleep, yet always the moment he was touched the rigidity was there. Finally, when going up to the hospital one day in a car the conductor informed Dr. Shrady that this man had been seen in a partially intoxicated state, when he held on to the strap as any other man would do. On arriving at the hospital Dr. Shrady found him still in his bent position. He ordered him, after the fashion of the day, to report for duty. He was more crooked than ever. He was then placed under an anæsthetic, straightened out and was entirely cured. Previously they had watched diligently for relaxation of the muscles, but were unable to detect it. He had exaggerated sensations, like the man presented by Dr. Smith, whenever he was touched.

DR. W. H. DRAPER did not wish to commit himself to an opinion without further examination of the case, but he thought it looked like one of hysteria.

DR. R. F. WEIR was reminded by Dr. Shrady's case of a man whom they had in a large hospital during the war who claimed to be aphonic, and was put to nursing. They suspected he might be shamming and watched him very carefully, but he passed through all the tests and the close watching without being detected. His papers of discharge were sent on, and had come back to Dr. Weir, who was to have given them to him the next day, but that very night a patient in one of the wards was seized with sudden hemorrhage, and the nurse came running over, crying out, "Doctor, so and so is bleeding!" It so happened that Dr. P——, whom the nurse supposed was on duty that night, could not be there, and his place had been taken by Dr. S——, who recognized the voice of this man. Consequently he was sent to the front instead of being discharged from the service.

DR. A. H. SMITH remarked, as bearing on the question of this being an assumed condition, that there was no apparent reason for it; the patient did not desire to be kept in bed, he had apparently made no effort to be retained in the hospital; he had tried to be of some service about the wards, and when it was proposed to burn his back with the Paquelin cautery he said he did not object if it would do him any good, and he had not opposed its repetition. His demeanor did not seem that of a malingerer, although they had suspected he was one. Hysteria had also been thought of, but as he had watched the case he had been inclined to the opinion that there was an intra-cranial tumor.

DR. DANA added that he thought it would be impossible for the man to simulate ankle clonus, which had been mentioned in the history; and with regard to all sorts of exaggerated reflexes being present in hysteria, suggested by one of the speakers, he said he thought that in hysteria in the male with paraplegic symptoms, the rule was that the reflexes were diminished, and when increased there was almost always a tremor. This man had no tremor at all; his hand was perfectly still.

This was very unusual with a hemiplegic hysteria. His mental condition, his attitude, and whole physiognomy were entirely different from that in cases of hysteria of the male which he had seen, and he had seen a good many cases at one of the city hospitals.

On examining for ankle clonus Dr. Dana could not find any evidence of it this evening, and Dr. Draper remarked that the reflexes did not seem to him much exaggerated. Dr. Dana added that if one found very decided limitations of the visual field, it would be strong evidence of hysteria. [The patient had then gone and could not be examined for this symptom.]

Abscesses Simulating Appendicitis from Rupture or Ulceration of the Gall-bladder.—Dr. F. Weir presented the details of three cases, two of his own and one by permission of Dr. Markoe, of perforation by ulceration of the gall-bladder with subsequent formation of abscess in the neighborhood of the right iliac fossa, thus simulating a perityphlitic abscess. In two of the cases the autopsy showed beside the lesion in the gall-bladder, due in both instances to retained gall-stones, that the passage of the effused bile downward had occasioned only a circumscribed peritonitis, and in one of the cases the matter, released in all the cases by surgical procedures, showed no trace of biliary coloring. The infectious influence of effused bile was also considered at length, and many cases were cited to show that in empyemic processes of the gall-bladder it was more severe than when the latter was merely distended by obstruction of the cystic duct—wounds or traumatic rupture of the gall-bladder being the least infectious from the escaping bile. The method of treatment in conditions where the lesion is recognized and the patient's strength admits of extended surgical treatment was detailed, and was corroborative of Courvoisier's recent deductions. Several other personal cases simulating appendical abscesses, but of a different origin, such as sarcoma with suppuration in right iliac fossa or near umbilicus, were given, and one particularly, of phlegmon of the broad ligament, where the initial symptoms strongly pointed to a perforation of the appendix, was commented on at length.

The Frequency of Perforation and Peritonitis from Gall-stones in Old Persons.—Dr. Herman M. Biggs said he had seen a number of cases post-mortem of general peritonitis following ulceration and perforation of the gall-bladder by gall-stones, and he had been impressed by the fact that nearly every case had occurred in old persons. These autopsies had not been at Bellevue, but at the almshouse on Blackwell's Island. The cases numbered four or five. The gall-bladder had been perforated, and one or more stones were found in the peritoneal cavity. Whether this peculiar experience was due simply to the greater frequency of gall-stones in elderly people than in others, he was unable to say.

Large Gall-stones entering the Duodenum by Ulceration.—Dr. W. H. Draper recalled two cases in which large gall-stones had found their way into the duodenum by ulceration. One was that of Dr. B——, well known to most present. There were no symptoms in this case until the stone, which was a large one, had dropped into the duodenum and given rise at once to symptoms of obstruction. The patient, having been perfectly well, was suddenly taken with severe pain and vomiting. Fecal vomiting came on within two days. Several surgeons saw him. He lived nine days. When the autopsy was made, the stone was found to have progressed downward about eighteen feet, and lay in the ileum.

He had seen a very similar case about three years ago with Dr. Yale. In this case the woman had had one or two attacks of biliary colic. Dr. Draper ventured to make the diagnosis of a large stone which had engaged in the intestine. She had symptoms of obstruction. The family were opposed to an operation until she had entered a state of collapse. A stone was found very similar in shape and size to that in Dr. B—— 's case, but not so far down. She had died, too, after a shorter illness—about five days. In each case a large ulcerated opening existed between the gall-bladder and duodenum.

Dr. Weir remarked that, as he remembered the case of Dr. B——, the interesting fact was revealed at the autopsy that had the abdomen been opened during life, the stone could have been readily found. Owing to the thickness of the walls, however, it could not be felt until the belly had been opened.

The President said he had never seen any cases at autopsy like those referred to by Dr. Biggs. Regarding Dr. B——'s case, referred to by Dr. Draper, he was reminded that a few years ago a doctor in the city showed him a stone of about the same size, which had caused the death of his father in the country. The patient was under the care of a country practitioner who did not suggest surgical interference, although, from what the son said, the symptoms were those of intestinal obstruction, and a stone could be felt in the neighborhood of the umbilicus. All that could be done in the way of an autopsy was to make an incision over this tumor, which was found to be a stone obstructing the intestine. It could not, owing to its size, have reached the intestine without making an artificial opening.

Dr. Weir inquired of Dr. Biggs whether, in the cases on which he had made autopsies, there was any circumscription of the effused material in the right iliac region, simulating perityphilitis.

Dr. Biggs replied no, that the peritonitis was general. He added that, although the patients had been inmates of the almshouse prior to the fatal illness, there had been no history of hepatic colic. In the last case, which occurred a month or six weeks ago, the patient was admitted to the hospital for what was supposed to be and what proved to be peritonitis. The autopsy showed the gall-bladder well filled with gall stones and an opening of considerable size over the fundus through which a large stone had escaped into the abdominal cavity. He had seen a number of cases like those cited by Dr. Draper, in which large stones had made a passage into the intestine, but he had seen none except those on the island in which the perforation had taken place into the peritoneal cavity. It had occurred to him as a possible explanation that reactive inflammation in old people was less marked.

When to Operate in Hepatic Colic.—Dr. F. P. Kinnicutt said that, *apropos* of Dr. Weir's paper, there was a point which he had raised in citing a case at the last meeting of the Society. The case was one of repeated attacks of hepatic colic. Most careful watching failed to show stones in the passages, there was no jaundice, no recognized distention of the gall-bladder until the last attack. The man died in one of these attacks, death being caused by a large cerebral hemorrhage. The hepatic colic was found to have been due to a large gall-stone firmly impacted in the neck of the gall-bladder. There was no ulceration; there was no obstruction of the common duct. The stone was so large that it would not pass from the ileum into the cæcum. If the patient had lived longer it seemed the final end must have been one of three things: ulceration into the duodenum and intestinal obstruction; ulceration and escape into the peritoneal cavity with fatal peritonitis; or atrophy and drying up of the walls of the gall-bladder surrounding the stone. He was rather disposed to advise an operation in similar cases.

Atrophy of the Gall-bladder about Stones.—Dr. Andrew H. Smith related a case, *apropos* of Dr. Biggs's remarks, upon atrophy of the gall-bladder about a stone. The patient was a woman in her eighty-first year, whom he first saw the past summer, when she was complaining of a good deal of abdominal pain, considerable abdominal distention, anorexia, nausea. On palpation he felt a tumor in the region of the gall-bladder as large as one's fist, very hard and very sensitive to the touch. He was absent on a trip to Europe six weeks, and when he came back learned that the patient had been pretty comforta-

ble during that time. Fever, which had never been very great, subsided, and the pain disappeared, but the tumor was still present, though somewhat smaller and not so tender on pressure. The patient told him that she had had repeated attacks of that kind during the past four or five years. He could make nothing out of the case further than to surmise that the gall-bladder was full of stones, and had atrophied and contracted down upon them, and now and then some of its structures underwent renewed inflammation.

Relation between Hepatic Colic and Malaria.—Dr. Joseph D. Bryant said the case which Dr. Kinnicutt had related reminded him forcibly of one with which he had been familiar the past eight years. The patient was a man in middle life, in perfect health as far as he knew except for certain attacks. These started about ten years ago in what seemed to be an attack of ordinary hepatic colic, although it was fair to say that he had suffered from malarial attacks prior to that time. Dr. Bryant saw him in one of the attacks for the first time about eight years ago. He was unable, however, after most careful search, to find any gall-stones in the fecal passages. For three years, subsequently, he had no further attacks. In the fall of 1888 they began again, and finally came on every day. An interesting fact was that they came in the afternoon. Dr. Janeway saw the patient with him on two or three occasions, and they came to the conclusion that the attacks were manifestations of malaria. The two facts on which this opinion was based were, 1, The man had no attacks when out of town; 2, No matter how severe the attacks might be, ten to fifteen minims of Magendie's solution relieved them. But the question of interest was whether malaria was really the cause of the trouble, or whether stones were present which caused paroxysms only when a malarial influence arose. Dr. Bryant had gone so far as to suggest an exploratory incision, and would have insisted on it had not the attacks ceased when the man went out of town. There had now been no attacks for three or four months.

Would Wait.—Dr. Weir said Dr. Kinnicutt's question raised the point whether we should perform an operation which was attended by some risk for a condition which was not known before operating to be dangerous. He would answer by saying that if the attacks rendered life a burden or unfitted the man for active duties, he would feel justified in resorting to a procedure which all must admit was attended by some risk. If life had not become a burden, the stone might remain in the gall-bladder a considerable length of time, or it might ulcerate happily into the intestine.

Dr. Kinnicut remarked that it might be too large to pass through the intestine.

Dr. Weir said it would be easier to tackle it when the trouble actually arrived. Besides, one did not know for a certainty that the stone was in the gall-bladder or cystic duct, although the symptoms might point that way. He once saw a case with Dr. Delafield and Dr. Partridge which looked very much as if it might be one of distended gall-bladder from stones. There was a history of repeated attacks, and he thought it not unlikely an operation would have to be done. Dr. Delafield, however, thought the trouble might be of catarrhal origin and advised them to wait. They waited, and the patient recovered. Again, Dr. Draper saw a case with him which he thought pointed very strongly toward operative interference. Dr. Draper, however, thought it right to try medical treatment a little longer, and between this and their handling the woman got better, and in forty-eight hours had recovered completely. There had been no trouble since. It might be that their examination had forced the gall-stone on.

Dr. Kinnicut asked Dr. Weir whether there was jaundice, and whether the stone was not in the common duct, to which Dr. Weir replied in the affirmative. Dr. Kinnicut went on to say that there was no evidence of obstruction in the common duct in his case; there was the strongest evidence of serious obstruction in the neck of the gall-bladder or in the cystic duct, and no evidence of a catarrhal condition.

Why should Biliary Calculi cause Inflammation in one Case and not in Another?—Dr. Delafield thought that which troubled the diagnostician was, why sometimes calculi stayed in the gall-bladder without causing inflammation while at other times they did cause inflammation. If they did not give rise to inflammation the worst which they could do would be to cause pain. But why in some cases they should cause inflammation and not in others was the great gap in our knowledge, and made all the difference with regard to the advisability of an operation. He knew a man who had been having his attacks of pain every year regularly for at least ten years, sometimes with jaundice, more frequently without. No calculi had ever been found in the stools, the gall-bladder had never been enlarged to any appreciable extent, and when the man had no pain he was perfectly well. It was, therefore, simply a question with him whether to endure the attacks of pain a short time or risk an operation. There was another point to be considered in discussing the advisability of an operation. Where calculi could not be found in the fæces, and there was absence of jaundice and tumor, he knew of nothing more difficult than to distinguish between attacks of so called biliary colic and intestinal colic. He doubted whether it was possible to differentiate between them in many cases with certainty.

Correspondence.

OUR BERLIN LETTER.

THE PRESENT ASPECT OF THE KOCH TREATMENT IN BERLIN —PROFESSOR FRAENKEL TAKES ISSUE WITH VIRCHOW AS TO CAUSES OF DEATH FROM TUBERCULIN — PROFESSOR LIEBREICH'S NEW REMEDY.

Berlin, February 19, 1891.

At the meeting of the Berlin Medical Society of February 18th, Professor B. Fraenkel delivered an address closing the discussion on his original paper concerning the Koch treatment, read in December last. "You have heard," said he, "the extended discussion which has been carried on for the last two months over my paper; reports of cases both favorable and unfavorable have been read to you; you have seen the demonstrations of pathological specimens by our President, Professor Virchow, and in speaking a few closing words at this time I can only touch upon a few of the more important points concerned in the unfavorable cases. First, then, the dosage cannot be taken as the only criterion in fatal cases. We cannot say that death has resulted in all cases from overdosing, for there have been deaths after only two or three injections had been given, of one milligramme each. These cases, however, are exceptions, and in the majority of fatal cases there has been a history of large doses with frequent increases. Second, you have been shown a pathological preparation in which was found caseous pneumonia, in the lungs of a patient who had received but a few injections. I would call your attention to the fact that a catarrhal pneumonia was not present in this case, and since caseous pneumonia is an affection requiring a longer time and some degree of chronicity for its development, we cannot regard it as possible that under the action of the Koch lymph, or as it is now officially known, tuberculin, such a caseous pneumonia should develop in a few days. If the tuberculin cause pneumonia, it would be of the catarrhal and not of the caseous variety, and we therefore consider that in the case brought under your observation by Professor Virchow, the pneumonia co-existed with the tubercular process and was not dependent upon five days' treatment with tuberculin. When we reflect how very frequently chronic tuberculosis and caseous pneumonia are found together at post-mortem examinations we are further confirmed in this opinion. Third, and most important, we have to consider the diffuse miliary tuberculosis exhibited

in a case which had been treated by tuberculin. Here the same argument applies with even greater force. Among the different forms of tuberculosis, the miliary has been regarded as the most severe. In the case mentioned the tuberculin had been given but twice. If the lymph had the power to cause tuberculosis we should certainly expect a mild form, instead of the most severe one known, after any such short course of treatment, and moreover, we must again regard it as physically impossible for such an extended form of the disease to follow the use of the lymph in any such short time as two days. Under the action of the tuberculin all tubercular tissue goes through a process of ulceration and necrosis and we can well conceive that if a diffuse miliary tuberculosis exist in the body there may be a very high grade of reaction following the use of tuberculin, but if such a patient die it cannot be said that the lymph has caused the miliary tuberculosis. It would be more accurate to say that the miliary tuberculosis was latent and that the patient died, not because he received the lymph, but because the disease had so underminded his strength that he could not rally under treatment. If tuberculin had the power to cause this form of the disease, it would be a very common thing at the present time, while the fact of the matter is, that many of us who are using the lymph constantly have not seen a single case of such an unfortunate complication.

"If I were asked what I think of the Koch treatment to-day I should answer, the more I investigate it the more I am convinced that it is what Koch claimed it to be, a successful method for treating tuberculosis in its incipient stages. We all know that it has been given to advanced cases, and we must admit that there have been some bad results. We must admit, too, that it may call into action a latent miliary tuberculosis. I ask you, however, to recall the history of the treatment of tuberculosis in your own practice up to the time of the Koch discovery. Have you had any satisfactory treatment? Have your patients recovered? On the one hand, we have Koch's treatment, with some dangers, it is true, but with the history of an enormous number of cases in which very marked improvement has taken place, and some in which apparently a cure has been performed. On the other hand, you have a vast array of remedies which have been tried for the treatment of this disease, and which have proved of no considerable value, either for improvement or cure. I therefore do not hesitate to pronounce Koch's treatment by far the most promising of any yet known for the treatment of tuberculosis in its incipient stages. For *all* cases of tuberculosis it is certainly not to be used, and we must with great care in accurate diagnosis select those cases which can truly be called 'incipient,' before using this remedy.

"Had I closed my address one week ago, I should have stopped here. Within the last few days, however, Professor Liebreich has sent me a new remedy, which when used subcutaneously for the treatment of tuberculosis of the larynx produces no fever, and seems to work in a most marvellous manner upon the disease. We have six cases under our observation which are receiving this new remedy, and at the next meeting of the Medical Society, Professor Liebreich will address you upon the subject."

Great interest was manifested in Professor Fraenkel's speech, and at its close repeated calls were made for Liebreich. For some reason the latter preferred to postpone any address upon the subject until the following week. The new remedy is said to differ from the Koch lymph in not being made from bacilli, nor in any way dependent upon them. When injected it produces no fever, but the local changes in tubercular tissue are as marked as those from tuberculin. It can be used either with or following the Koch treatment, or entirely independently of it. It is thought it will possess the good qualities of tuberculin without its dangers.

Professor Virchow demonstrated the larynx and other organs of a patient who had been treated with tuberculin. On the left vocal cord was a small, fresh ulcer, and scattered through the intestinal canal were several ulcers, some fresh, some partly, and some entirely healed.

The strong reaction against the use of Koch's lymph which set in some weeks ago seems to be losing its force, and renewed confidence is felt in the remedy under the influence of reports from Berlin and provincial clinics where the method has had a more extended trial. Much greater care is used than at first in selecting cases for treatment. It is refused to all who show a pronounced hectic fever, or who have the physical signs of extended tubercular infiltration in the lungs. The Koch syringe has been proven to be inaccurate, and is gradually being replaced by improved models. The Mayer syringe may be mentioned as one of the latest improvements; it is divided on the glass cylinder, like the Koch instrument, is more easily cleaned and kept aseptic, and is absolutely accurate. The disk is of asbestos, and can be expanded to fill the cylinder air-tight by turning the piston. As a perfect syringe for hypodermic use it leaves nothing to be desired. Under the influence of improved instruments, greater accuracy in dosage, and stricter limiting of cases for treatment, there has been a great improvement in the statistics, and greater confidence in the remedy is felt on all sides.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE HUNTERIAN ORATION AT THE COLLEGE OF SURGEONS—MR. TREVES AS A CONSERVATIVE IN SURGERY —DISCUSSION ON APPENDICITIS AT THE CLINICAL SOCIETY—RANK AND TITLES OF ARMY MEDICAL OFFICERS —THE MIDWIVES BILL—THE UNIVERSITY OF LONDON.

LONDON, February 21, 1891.

THE Hunterian oration for this year at the College of Surgeons was delivered on Saturday last by Mr. Jonathan Hutchinson, F.R.S., late President of the college. An annual oration on one set theme renders originality of treatment rather difficult, but Mr. Hutchinson managed to impart fresh interest to his subject, as might have been expected from his own versatility and originality. He urged that the Hunterian oration might, with propriety, be given in honor of the Hunter family rather than in that of one of its members. He would go further and say that it should not forget the Paul family either, for Paul was the maiden name of the mother of William, James, and John Hunter, and of the grandmother of Joanna and Dr. Matthew Baille.

Had there been no John Hunter, observed Mr. Hutchinson, William would have been accounted a genius. His fame was great, but his brother eclipsed it. The similarity in the tastes and endowments of the two brothers was remarkable. Both were resolute to base practical knowledge upon anatomical and physiological research; both zealously taught anatomy; both were indefatigable collectors of facts; both made large museums. The museum collected by Dr. Hunter, and bequeathed by him to the University of Glasgow, was second in value only to that now possessed by the College of Surgeons here.

Mr. Hutchinson protested against the custom of Hunter's biographers to represent him as the uncouth and uneducated son of a Scotch farmer, and as having been brought up for the trade of a cabinet-maker. It was possible, but not certain, that before coming to London he had wasted two or three years by working as a cabinet-maker in Glasgow. There was no doubt that in boyhood he had received a good Scotch education in elementary matters, and that during his Glasgow life he must have had fair opportunities for its further development. It was incredible that a brain so active, with such a thirst for knowledge and such a love of thought, could have been guilty of any material self-neglect during boyhood and youth.

One of Hunter's secrets of strength was his patience; he spoke on one occasion of having listened for an hour

to the complaints of a patient who consulted him for impotence. Two other important traits in his character were then pointed out. He was fond of pictures, though there was no evidence that he himself possessed any artistic skill. Both the brothers set a high value upon artistic illustrations of anatomical and pathological subjects. John Hunter never published a single paper or book, the subject of which would admit of illustration, without accompanying his letterpress with a liberal supply of plates. He engaged an artist to live with him in the house, and the engagement was prolonged to fourteen years. Another point was the zeal which he displayed for the record in print or, at any rate, in manuscript, of all observations. He was a prolific author, and left behind him many volumes of notes. It might seem a bold step to seriously compare Hunter with Aristotle, and he was unquestionably far behind the Greek in the breadth of his attainments and sympathies; while the one carried habits of impartial investigation into all departments of knowledge, the other, when he left his own domain, sometimes exhibited only the strength of prejudice. But where they met on common ground the two showed habits of thought and intellectual powers not very unequal. Both were systematic and enthusiastic zoölogists in times when the study of zoölogy was the pursuit of very few. Both saw clearly that advance in natural history knowledge could be made only by the collection of facts, and, realizing that such advance was well worth the effort, both set themselves zealously to work. It had been asserted that between Aristotle and Kant no metaphysician of original power had appeared; in like manner we might say, in reference to scientific zoölogy, that there was no one between Aristotle and John Hunter. In admitting Hunter's inferiority in scope of attainment, we must not forget the great difference in their occupations.

Aristotle, though the son of a doctor, did not practise physic, and was liberally supplied with funds. During the most prosperous part of his career his pupil, Alexander the Great, not only supplied him with money, but collected specimens for him in distant lands. As had been remarked by Sir Alexander Grant, never before or since was the endowment of research on so liberal a scale. Our countryman had to earn every pound he expended in zoölogical science by the exercise of a toilsome profession. In one characteristic, Hunter and Aristotle greatly differed. Aristotle carved for himself, in Plato's school, the cognomen of the "Reader." Hunter acknowledged that he did not read much. His writings were all from his own observation. He scarcely ever made a quotation, and rarely mentioned a name. As to how far this neglect of professional literature was an advantage, and how far a loss, there might possibly be some difference of opinion. Mr. Hutchinson said, however, that he must admit that Hunter's work on the Venereal Diseases, though abounding in sagacious thought, was in many respects behind the knowledge of his day.

It had been said many times that the source of Hunter's success lay in his combination in one person of the qualities of thinker and observer. Every page of his writing went to prove that he was an observant man. "Don't think, but try," was one of the now celebrated sentences in which he inculcated upon one of his friends the duty of experiment and observation. In it the word "think" must of course be understood in its lower sense as applied to an untested belief or supposition, a sort of taking for granted. Hunter never uttered one syllable in disparagement of careful thinking. There were, however, other qualities of great importance which were elements in Hunter's character, and first among these must be placed his insatiable thirst for knowledge. This was innate, it was born with him, just as were the color of his hair and the form of his features. Was it an advantage to him or a reverse that he was brought up on a farm, and that all the tuition he got was at a parish school? Probably his country pursuits not only favored his physical development, but were useful in forming his powers of observation and self-reliance. As to the school, much would depend on the schoolmaster, but it was unquestionable that Hunter was fairly well versed in the elements of school education, for he mixed in London with men of high training, and was a prominent fellow of the Royal Society. University training at the proper time might have been useful to him. We knew what Hunter, unaided by this training, did actually accomplish. We should err very seriously if we concluded that he would probably not have accomplished so much had his youth been spent at a university instead of in a cabinet-maker's shop. The possession of classical knowledge did not encumber the minds of Bacon, of Harvey, or of Newton, and Mr. Hutchinson expressed his conviction that had Hunter obtained it at the proper time, it would have been greatly to the advantage of his readers and himself.

Mr. Treves as a conservative in surgery is somewhat of a novelty. Had I been asked to name Mr. Treves's favorite surgical virtue, I should have replied that probably "boldness" was the attribute he esteemed most highly in a surgeon. I should, it seems, have done him an injustice, for at the last meeting of the Clinical Society he posed as the opponent of undue surgical interference in certain cases. The operation under discussion was that of removing the vermiform appendix (appendectomy), one which may be said to be associated in no small degree with Mr. Treves's name. A discussion took place on the subject, following the reading of communications from Mr. Herbert Allingham, Mr. Bland Sutton, and Mr. Andrew Clark, in which cases of appendicitis were related. Mr. Treves remarked that Mr. Sutton's observation that one of his cases of appendicitis had "been treated by the methods ordinarily adopted by physicians" had called forth what was almost a smile on the faces of some of the audience. But the "medical" treatment of typhlitis was successful in very many cases, and to treat all these cases surgically would only lead to disaster. The great majority of cases admitted into the London Hospital during the last ten years had recovered under medical measures, and there was no doubt that the epidemic of removal of appendices which had prevailed in some quarters had been extreme. If mere acuteness of symptoms were a guide to operation, many cases would be dealt with where no disease of the appendix would be found; on the other hand, he had known patients to continue at work till the bursting of the appendix. Rectal examination would aid in arriving at a differential diagnosis between trouble in the cæcum and appendix. Reflex pain in the testis, labia, or neck of the bladder should be looked for. He deprecated interference before the fourth or fifth day, and protested against the notion that when anything went wrong with the appendix that the result must either be operation or death. He expected every day to hear that a piece of ureter had been removed in the course of the operation, for it was perilously near.

Dr. Coupland said it was quite refreshing to hear a surgeon approving of medical methods, for physicians had been taunted over and over again with persevering in the medical treatment of these cases. His own observations had led him to believe that trouble in the cæcum itself was extremely rare. He admitted that many cases recovered, but in these he thought the mischief was also in the appendix, and he knew of no sign or symptom which would differentiate one class from the other. What were the indications which justified the calling in of the surgeon? First, those cases, mostly in young people, in which the first symptom was acute peritonitis of short duration—"fulminant" cases; such a case might be one of perforated appendix. The aid of the surgeon should also be sought in cases of suppuration. The debate on this subject is to be further continued at the next meeting of the society.

The recent deliverance of the Secretary of State for War on the subject of the Army Medical Department is not likely to settle the questions at issue. He proposes to grant the compound titles advised by the commission

(Surgeon-Colonel, etc.), but not to give substantive rank to army medical officers. Such a compromise cannot possibly prove satisfactory in view of the extent to which discontent has spread.

The Government has announced that it will not support the Midwives bill; of course this means that the measure will not pass this session, so the question of setting up a fresh grade of unqualified practitioners is postponed for the present.

The reconstruction of the University of London still lags. The latest scheme is satisfactory to the two medical colleges, but not to the two great teaching colleges in London (University and King's College), thus simply reversing the position taken up when the preceding scheme was mooted. We seem, in fact, as far as ever from a settlement of the matter.

INSTITUTIONS FOR DRUNKARDS.

To the Editor of the Medical Record.

Sir: It is to be hoped that Dr. Crother's article, which appeared in the Medical Record of February 21st, under the head of "Institutions for Drunkards," may awaken greater interest in the medical profession regarding the subject of inebriety. Proven to be a disease "susceptible of treatment and cure," it lays legitimate claim to our professional skill, as healers of the sick; and the weight of responsibility becomes greater, in view of the satisfactory results which a better knowledge of its pathology now enables us to secure.

Even the necessity for an asylum or other institution in which to confine these patients is no longer felt.

That they can be cured without these provisions for restraint is being daily demonstrated in this State (Ohio), where not only inebriates, but drug habitués, enjoy the same privileges and liberties that are accorded other patients.

That the results are all that could be desired, is shown by the facts that ninety-seven per cent. of all cases coming under treatment are cured; that less than five per cent. relapse; and that the time required to effectually destroy the depraved appetite—leaving the individual with his accustomed liquor or drug never again a necessity—rarely exceeds three weeks. W. F. White, M.D.

Marysville, O.

"PREACHING AND PRACTICE."

To the Editor of the Medical Record.

Sir: Among those who read the Medical Record and admire its cosmopolitan spirit, it is doubtful if there are many who fully appreciate it when it chooses to indulge in innuendo and *double entendre*. In the editorial of the 7th ult., under the above caption, it is stated: "We advise every one of our readers to be a total abstainer. But we do this on physiological grounds, and not because the physician must necessarily practise all that he preaches." Perhaps only the man who has been tested can fully know how difficult a task it is to appear fifty-two times each year before a censorious public, armed *cap-a-pie* in editorial panoply warranted impervious to all the critical shafts and goose-quills that, with more or less precision, may be hurled at it.

But those who have "enlisted for the war," in the army of the "world-betterers," and have taken the Medical Record "for better or for worse," and embraced in good faith its creed, "The physician should be either a Christian or a philosopher," these simple and single-minded souls would be glad to know just what it intends to teach, and whether while

> "It points the steep and thorny way to Heaven,
> Itself the primrose path of dalliance treads."

In the light of history there seem good grounds for encouragement to the "world betterer;" but we learn from the same great source that we must either progress or retrogress, that eternal vigilance is the price of virtue as well as of liberty, and that many proud nations in the past have permitted, through their constituent members, the germs of degeneracy to take root, resulting finally, as Mr. Wegg would say, in "their decline and falling off."

These dire results have been ascribed to the selfish, the ambitious, the haughty, and the voluptuous, but never to the "world-betterer."

Clergymen sometimes preach the right and practise the wrong, but did it ever fail to result in mental and moral bankruptcy?

"But," it is said, "alcohol is all wrong, and we hope the journal will continue its propaganda against it."

This statement, whether ironical or not, if it means alcohol merely as a beverage, will, in this age of the world, probably be endorsed, and its truth be both preached and practised by every true philanthropist and philosopher; but it is likely to be generally inferred that the Medical Record has some occult reason for putting the bottle and the weed to its own lips while withholding them from others. Regarding the physician's right of refusing a dose of calomel for himself, although he may have prescribed it for his patient, this seems a sort of ethico-pharmacal incompatibility; but it may perhaps pass in accordance with the axiom, "There is no disputing about tastes."

I hope that these friendly remarks will be received in the same spirit—remarks which are chiefly justified by the supposed privileges of an Old Subscriber.

Leavenworth, Kan.

[We have so often stated our opinion as to the use of alcoholic drinks that we may be pardoned if we sometimes fail to treat the subject with due seriousness. People are better without alcohol, but there is a contingent of grown up persons who can drink it temperately without harm. This is what physiology teaches and medical experience confirms. These have always been the views expressed in the Medical Record.—Ed.]

IS IT REALLY AS BAD AS THIS?

To the Editor of the Medical Record.

Sir: The article on "Medical Cannibalism," in the Medical Record of February 28th, interests me. It has interested me for some years. It is nearly impossible now for a man to be "the beloved physician," as of old. So many villains have crept into our profession unawares, and legally, and their methods are so sharp, that in order to compete with them a man has necessarily to be a thorough-bred rascal, and a liar that would even put Ananias and his *frau* to shame—that is if he would hold his own; and why, because the public demand it. If you are called into a class of families that are snobbish, and answer honestly and frankly that your patient has congestion of the lungs, you will, on the return of your second visit, find "Dr. Snide," the eminent specialist for lung diseases, on hand, and you get the "G. B." By the way, "Dr. Snide" is a much younger man than yourself, and has but recently, or within two years, come through his Alma Mater as grist. And if the patient dies, "Dr. Snide" will tell that it was caused by calling "Dr. Commonplace," who made a mistake in the diagnosis, that it is "pneumonia" and not "congestion of the lungs;" and so it goes, day by day, and case after case, with these sharks, whose method of advertising is by the underground railway system of servant girls, "cappers," and "steerers." Every honorable physician can testify to this.

Often when you are called into a new family and you go straight forward honestly about the practice of your profession, your views are sounded as to the propriety of the different "pathies." You answer candidly, not knowing your family, that you do not practise "both ways." Upon your second visit you are bowed out with insulting

remarks about old-time physicians and allopath medicines, and your place is supplied by "Dr. Loose-'em," whose gold-rimmed spectacles, kid gloves, and sweet medicines make a smoother pathway to the grave. When I was a student in medicine, twenty five years ago, there was a little boy running around the street I lived on, ragged, dirty, and with his coat-sleeve to his little, catarrhal nose the greater part of the time.

In a medical sense he was a "blighted ovum." This little wretch studied medicine and graduated. Three years ago a young lady, a member of the "four hundred" in our place, was afflicted with too much lover. I always believed this "B. O." sent her to me. The young lady was violently hysterical, and I simply prescribed tonics and nervines, as I am not in the abortion business.

The young lady returned to this shark, who said that my "treatment was good as far as it went, but did not go far enough." His, or some other person's, went far enough, and I received the credit for not knowing much.

Notice, again, if a physician has a serious case in a paying family how these villains will stir up dissension in that family by the neighbors who come in "to sympathize," as the devil sympathizes with lost souls: "Eureka, I have got you."

I had just such a case of pneumonia. The neighbors used the rack and thumbscrews upon the family to get me to call "Dr. Sneak." At last I gave my consent, as the constant chafing from the neighbors in the sick-room was worrying the patient to death, and I could not be there constantly. "Dr. Sneak" could not come that day, but gave them medicine—"morphine"—and told them to dismiss me and he would come the next morning. All honor to the invalid and the family, they saw through the dodge, and "Dr. Sneak" can never enter their household.

This same "Dr. Sneak" advised another family not to pay my bill, as I had made an error in diagnosis and was only coming there to run up a bill. He promised to back the family up in non-payment, but did not when the law was invoked to collect the bill.

This same "Dr. Sneak" nearly killed another patient of mine. The family were giving my medicine and his also at the same time; both contained opium. These men, gentlemen, are not what we ordinarily call quacks, but are "consistent members" in State orthodox societies. Another orthodox member secretly advertises medicine at one dollar a pint to prevent conception; but his influence with the public is so extensive and the law's delays are so embarrassing that no one wishes to prosecute him. The entire community, church members and all, would be so enraged at a person who would prosecute him that it would break his business up. This shark is viewed by these saints as an immoral necessity, in about the same view as some look upon a licensed house of ill-fame.

Much more can be said, but I forbear.

JUSTICE.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 1, 1891, to March 7, 1891

HORTON, SAMUEL, Major and Surgeon. By direction of the Secretary of War, granted leave of absence for two months on surgeon's certificate of disability. S. O. 49, par. 7, A. G. O., Washington, D. C., February 4, 1891.

LIPPINCOTT, HENRY, Major and Surgeon. By direction of the Secretary of War, is relieved from duty at Fort Union, N. M., to take effect upon the final abandonment of that post, and will then proceed to Fort Adams, R. I., and report in person to the commanding officer of that post for duty as Post Surgeon, reporting by letter to the Commanding General, Division of the Atlantic. S. O. 46, par. 9, A. G. O., Washington, D. C., February 28, 1891.

DAVIS, WILLIAM B., Captain and Assistant Surgeon. By direction of the Secretary of War, the extension of leave of absence granted in Special Orders, No. 22, February 5, 1891, Division of the Atlantic, is further extended one month. S. O. 46, par. 7, A. G. O., Washington, D. C., February 28, 1891.

TREMAINE, WILLIAM Y., Major and Surgeon. Having been found, by army retiring boards, incapacitated for active service on account of disability incident to the service, is, by direction of the President, retired from active service this date, under the provisions of Section 1251, Revised Statutes. S. O. 4, par. 19, A. G. O. Washington, D. C., February 27, 1891.

LOSSING, LEONARD Y., Major and Surgeon. Having been found, by army retiring boards, incapacitated for active service on account of disability incident to the service, is, by direction of the President, retired from active service this date, under the provisions of Section 1251, Revised Statutes. S. O. 4, par. 19, A. G. O., Washington, D. C., February 27, 1891.

COONN, HENRY M., Major and Surgeon. By direction of the Secretary of War, will report in person to the commanding officer at Fort Adams, R. I., for temporary duty at that post, until the arrival of a successor to Major Samuel M. Horton, Surgeon, when he will return to his proper station. S. O. 45, Par. 8, A. G. O., Washington, D. C., February 27, 1891.

ELBREY, FREDERICK W., Captain and Assistant Surgeon. Having been examined by a board of officers, and found physically disqualified for the duties of a surgeon, with the rank of major, by reason of disability incident to the service, is, by direction of the President, retired from active service with the rank of major, under the provisions of the Act of Congress approved October 1, 1890, to date from February 24, 1891, the date from which he would have been promoted to the grade by reason of seniority if found qualified. S. O. 45, par. 6, A. G. O., Washington, D. C., February 27, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 7, 1891.

RUTH, M. L., Surgeon. Granted one month's sick leave.

EVANS, S. G., Assistant Surgeon. Detached from the Naval Academy, and ordered to the Monongahela.

PRICE, A. F., Surgeon. Ordered to the Monongahela.

HARRIS, H. N. T., Assistant Surgeon. Ordered for examination preliminary to promotion.

PICKERELL, GEORGE MCC., Assistant Surgeon. Ordered for examination, preliminary to promotion.

AUZAL, ERNEST W., Passed Assistant Surgeon. Ordered to the Lancaster.

NORTH, JAMES H., JR., Assistant Surgeon. Ordered to the Lancaster.

GAINES, JAMES H., Surgeon. Ordered before the Retiring Board, March 12th.

Santoninoxime.—This is the name of a substance prepared by Dr. Cannizzaro by the action of chlorhydrate of hydroxylamine on santonine. Santoninoxime is a white crystalline substance, soluble in alcohol and ether, but dissolving in water, whether acid or alkaline, with difficulty. It is stated that this substance possesses the same action in the intestine as santonine, but owing to its lessened solubility it is much less poisonous, and it should therefore be preferred to santonine. Its dose as an anthelmintic is three times as large as that of santonine. —*Journal de Médecine de Paris.*

THE POSSIBILITIES OF MEDICINE.[1]

By T. GAILLARD THOMAS, M.D.,

NEW YORK.

GENTLEMEN OF THE GRADUATING CLASS, colleagues of a half-hour's birth, who now for the first time open your infant eyes upon the future which is to be at once the arena of your efforts and the criterion of your success, in the name of the faculty of the distinguished institution, of which to-night I am the mouthpiece, welcome—a warm and cordial welcome to the ranks of medicine!

The great Alexander Hamilton, who fell before the deadly pistol of Aaron Burr, was said by an eloquent contemporary to have "bowed before the force of an imperious custom." Like him I stand before you to-night, in obedience to an unwritten law which calls for an address at a medical graduation, on the part of one who, it is assumed, is able to speak to the young graduate words of advice, encouragement, and warning.

May the wisdom of your teachers not be impugned by their choice of Mentor, and may I be inspired to say something which may in the distant future, as you ply your trying calling, come back to your memories with sustaining power, with pleasant recollection, and with inspiriting influence!

The noble and exalted character of the ancient profession which in this hour enrols your names among its votaries has too often been set forth by writers and speakers to need allusion on my part to-night. The devotion which it calls forth from you, the singleness of purpose, the purity of life—all these have been over and over again recited to audiences just such as that which now graces this hall, by more ornate pens and by more eloquent lips than mine. Elsewhere, then, must I seek my theme if I hope to engage your attention or to excite your interest; and in this hope I select from the large field of exhausted topics "The Possibilities of Medicine."

Has it ever struck you as a remarkable fact that many professions fill their ranks, even in this utilitarian day, in consequence of the romance, the dangers, the chances of glory, the opportunities for heroism, the lustre, and the renown which are possibilities in them; in spite of manifold dangers, hardships, and self-sacrifices to which they expose their followers? At this very hour, while our statesmen bemoan the neglected farms of Vermont, New Hampshire, and Massachusetts, located as they are in regions remarkable for beauty and salubrity, men prefer to the quiet lives which their cultivation would cause them to lead, the hard and dangerous profession of the sailor, than which no life could entail more of suffering and of trial. Did our country need volunteers to-morrow, there would be no lack of men who would, for a mere pittance, expose themselves in the ranks of her armies; and the fisheries of all countries are richly supplied by youths whose lives are constantly sacrificed in this hazardous pursuit of a precarious living. The human mind craves just such excitement as is afforded by a journey into Darkest Africa, or by a voyage to the icy north in search of an open Polar Sea.

The magnificent rewards which await the painter; the immortal fame which lies fallow for appropriation by the successful sculptor; the glorious future which is open to the great architect, are enough to give charms to the wretched attic and solace to the impoverished board of the hard-laboring aspirant. How many a gallant youth in this hall would yield up his life willingly to live in history with the fame of Sheridan? how ardently would not another strive through a lifetime of labor and of waiting to lay his country under the debt which it owes to Farragut? and what effort would be too great to secure to another the evergreen crown which adorns the memory of Longfellow? Arms, literature, art, law, divinity, all have bright and glorious rewards for those who have the courage to aspire to them, the patience to suffer for them, the industry to work for them, the genius to obtain them.

Think you that the science of medicine, founded four hundred years before the birth of Christ, the chosen work of our Saviour himself, the most far-reaching and benign of all modern pursuits, stands alone in its inability to reward its votaries? Far from it! Look back with me into history, and I shall not be called upon to take you into the fields of ancient history even; and it will go hard but I shall make you agree with me that of all callings, all pursuits, all professions, the rewards of medicine are greater, more lofty, more desirable, and more enduring than those of any other in existence.

Before proceeding further with our argument, let us agree as to what we will mutually fix upon as the highest and most desirable of earthly rewards. Had this question been put to Buddha, that highly civilized Hindoo would probably have replied, "To be considered a god among men;" Confucius and Mohammed would probably have said, "To be the founder of a religion to which millions would bow;" Cæsar and Charlemagne, "To rule the world;" Washington and Franklin, "To have set up a form of government to be the prototype of the nations for ages to come;" Napoleon I., "To be considered the greatest soldier and statesman that the planet has ever known, even though the attainment of the end should involve wading up to the armpits through blood." You and I, representing as we do the two great moral centres of the universe—New York and Brooklyn—will agree that he who has done the greatest good for his fellow-man, has, in the doing of it, won the greatest reward in Earth's possession, even though no mortal man know of the deed but him!

As you and I look upon the great picture by Vibert, entitled "The Missionary's Story," we see the crown of glory, the diadem of success, not upon the head of the honored and decorated abbot, but upon that of the ragged servant of the cross, with his body deformed by torture and his frame wrecked by toil.

The forces of civilization work hand in hand for the common good. Since the lifting of the veil which, under the name of the Dark Ages, shut out the benign light of law, of progress, of the fine arts, and of religion, how nobly has each of its servitors striven for the re establishment of all that was good and elevating among men! It was as if all forces had combined to woo back the smile of God upon the earth! Let us see what the medical art has contributed as its quota of work for the good of society.

Where are now those dreadful epidemics of the plague described by Thucydides, Procopius, and later by Defoe, which desolated Athens, Florence, and London; and, in

[1] An Address delivered before the Graduating Class of the Long Island College Hospital, March 12, 1891.

the reign of Justinian, are said to have lasted for thirty years, and to have destroyed, according to an estimate regarded as reasonable by Gibbon, nearly one hundred million lives? Gone from the notice of the world, and although, even as late as 1835, showing its horrent front in Alexandria, blocked out from civilized Europe, and reduced absolutely to insignificance by our agent, Hygiene!

Where now is the fiend of cholera, represented by painters and by poets as a fell hag, who, with pallid cheeks and lurid eye, marched, torch in hand, into the hearts of the great seaports of the world, sowing death and sorrow broadcast in her path? Almost a thing of the past! Limited, controlled, and almost wholly imprisoned in that fateful eastern land of Asia, where the demon of disease seems to fight his last fight for existence!

Where is now that yellow "scourge of God," which, only two decades ago, made its home in the lovely city which looks out upon the delta of the Mississippi; made occasional excursions to Mobile, Pensacola, Savannah, and Charleston; at times tramped up the borders of the great river and laid Memphis in sorrow; and, in the beginning of this century even, reached New York and caused its authorities to fence off a portion of the town and call it the infected district? Seized by the throat by our servant, Quarantine, and told in no uncertain terms, "Thus far shalt thou go, and no further!"

Where is to-day that loathsome destroyer of life and of beauty, small-pox, which a century ago decimated nations, entering households and admitting of no escape, doomed the loveliest to death or disfigurement; and scarce more than a century ago, with unbridled insolence marching into the halls of Versailles, laid her polluted hands upon the monarch on his throne and dragged him down to ignominious and revolting death? Lashed to heel by our agent, Vaccination, and, like whimpering hound, held securely in leash.

What has become of typhus, jail, ship, or spotted fever, which doubled the horrors of the horrible sea voyage, and made room in jails and prisons for others to replace those whom it sent to Potter's Field? Swept out of existence as thoroughly and as surely as are to-day the three great moral blots upon the fair escutcheon of civilization, slavery, duelling, and polygamy.

But I must cease my enumeration, though it is difficult for one who loves his calling and glories in its conquests to do so. One more illustration, one which will come closer to the heart of every man among you who loves woman, and surely he who does not is none, and I leave this part of my subject. A few, a very few years ago, the graveyards of all lands, from the most savage to the most civilized, were filled with the bodies of women gone to their last account in the most interesting period of their existence. The very name of puerperal or childbed fever brought the shadow of fear to the face of the bravest man, and through its baleful influence scarcely a hearthside in our land but had a place which stood vacant. To-day, thanks to the greatest of medical agencies, Antisepsis, even in the large lying-in-hospitals of London, Paris, Berlin, Vienna, St. Petersburg, and New York the disease is almost unknown! Where, even as late as ten years ago, fifty were lost, less than one life is lost now!

So wonderful, so startling, so extraordinary are these results that I almost admit to my mind the fear that the non-medical portion of my hearers may suspect me of boasting as I read the record of the proud achievements of medicine during the last hundred years. I have but to appeal for support to the large medical contingent of my audience, and they will bear out the assertion that my claims are even less exacting than they might with justice have been.

You may contend that the very extent of this enumeration of the conquests of medicine proves that the possibility of achievements in the future must, of necessity, be greatly curtailed. This is far from true. There is an old French adage which declares, "Plus on s'élève. plus l'horizon s'avance;" "The higher one climbs, the more extended becomes the scope of vision." One great initial discovery often elevates the students of a science to heights not dreamed of before, from the elevation of which limitless space unfolds itself to view. Think of the secondary discoveries rendered possible by the initial discovery of the microscope, of the telescope, of the Copernican system, of the circulation of the blood, of steam, and of electricity.

When the grand fact was recently established that diseases were transmitted from individual to individual by organisms, which have been styled "bacilli;" that by the growth of these organisms diseases were perpetuated upon the earth; and that by their destruction the affections to which they give rise may be prevented, one of the greatest discoveries of any age was made; one of the most sudden elevations of investigators, with resulting expansion of view, was accomplished that the world has ever known. By it you stand to-night upon a plane far more elevated than that which even the youngest of your teachers occupied upon his graduation. Your possibilities in medicine are proportionately greater than his were; be it your function to profit by your good fortune!

It requires no prophet's power to foretell the fact that the science of medicine, which up to the beginning of the seventeenth century stumbled, foot sore and weary, along its tedious way, with little enterprise or progress; which in the next hundred years began to show decided evidences of awakening power; and which during the nineteenth century has made great and signal strides along the avenue of improvement, stands at this hour upon the threshold of an era which will belittle all the past, and accomplish in one decade of the future more than a century has previously brought forth. I make no reference now to work actually performed by Pasteur and by Koch. I allude only to the principle which underlies the labors of these great men; to the initial discovery which has rendered their secondary discoveries possible. The so-called discoveries of Pasteur and Koch may in the future rank with the fascinating tales of the "Arabian Nights." It matters not if they do; the great ball of knowledge and of truth has been set in motion, and all the powers of earth, if arrayed against it, could not check it in its irresistible progress.

I have received so many kindnesses from my confrères in Brooklyn, and I have so many loyal friends and true in this good city, that I feel to-night as if I were talking to a set of people to whom I could speak confidentially, as if in my circle of intimates, and say what by the world at large might be viewed with critical eyes Feeling so, let me venture to tell you this: Were I offered to-day by some great power the accomplishment of one wish, I think that I would select the destruction of the process by which alcohol is created. I know full well that the most cruel, the most treacherous, and the most vindictive of all the races of the earth are the most temperate; for example, the Hindoos, the Turks, the Arabs, and the most brutal of all savages, the implacable North American Indian. But, putting advantages and disadvantages into mental scales, I should select, as the wish nestling closest to my heart, the abolition of alcohol. If this were denied me, I would choose the power of stamping out forever those contagious diseases which fill our graves with curly heads and dimpled cheeks, and our homes with sorrow that knows no comforting. I would destroy those terrors of the household, scarlatina, diphtheria, and the host of contagious maladies which go hand in hand with them. The first of these wishes is impossible of attainment. But what of the second? Gentlemen, the way to its accomplishment is open to every man with willing hand, determined mind, and intelligent brain who stands before me now. Surely it is not too sanguine a prediction that the next century may see the extinction of contagious diseases.

I have told you how much the science of medicine has done for the prevention of disease. Listen now while I

point out to you how much remains for you and your contemporaries to accomplish.

Although by no means proven, it appears probable, that in the animal system there are elements which furnish food for certain organisms, styled bacilli, which, being attacked by these, help them to flourish so luxuriantly that their multiplication excites a tremendous reaction in the economy, which often ends in death; and that these elements once being destroyed, do not often reproduce themselves, and the recurrence of a successful invasion by that particular variety of bacillus is not again possible. How else can we account for the immunity secured against second attacks from the occurrence of one invasion by small-pox, varicella, whooping-cough, scarlatina, measles, and other contagious diseases? It was probably in this way that the prevention of small-pox by vaccination was accomplished.

Jenner, finding out that a disease of the cow, called vaccinia, used up in the system of milk-maids the food upon which the germ of small-pox lived; and believing in the old doctrine, "in time of peace, prepare for war," systematically laid waste the country before any future small-pox raid could start out upon its course, and rendered invasion impossible.

This appears to be a philosophical and satisfactory explanation of the method of protection accomplished by vaccination, and one would have expected that ere this a law would have been established with regard to the matter, and other similar discoveries made. Vaccination was discovered in 1799; since that time not one other contagious disease, unless the claims of Pasteur and of Koch should prove valid, has been prevented by the development of this brilliant idea! What a wonderfully rich and fascinating field of labor here opens up before the ambitious aspirant, and how promising its future appears!

But this is not the only way in which diseases have been checked. In certain maladies the pabulum of disease germs, while not destroyed beyond the power of reproduction by one attack of a disorder, appears to be to a great extent damaged in quantity and quality by certain drugs. Thus we see the salts of mercury greatly limiting the development of "lues venerea," and the bark of the cinchona tree to a certain extent controlling that curse of our country, malaria. And yet, strange as it may appear to you, of the so-called specifics in medicine these two stand entirely alone. I challenge the mention of any others.

Here again I direct your eager eyes up an avenue leading to fame and usefulness, scarcely less promising than the one previously mentioned; an avenue in which industry and genius have full scope for exercise, and one filled with rewards which must satisfy any truly noble ambition.

But you will say this very paucity of result proves the difficulty of the work; it is easy for a speaker to point out the way and to say "go thou and follow it;" how are we to solve a problem which has already proved so difficult of solution? Your elevation is greater than that of your predecessors; the scope of your vision is much more extended. Jenner's discovery was the result of empirical observation; the discoveries of Koch are guided by the pure and certain light of science. You stand not where Jenner stood, but where Koch stands.

If it be true, and there is no reason why it should not be so, that by previous destruction of pabulum in the blood, either by the action of drugs or of ptomaïnes, or by the discovery of phagocytes, or opposing bacilli, the invasion or successful advance of the germ-elements which create contagious and infectious diseases can be controlled, a field of labor will be opened to the physician which will make of medicine the most fascinating of callings.

The future is pregnant with promise. Young aspirant for the glory, the greatness, and the honors of that future which like a smiling landscape spreads out before you to-night, "I tell you that many prophets and kings have desired to see those things which ye see, and have not seen them; and to hear those things which ye hear, and have not heard them."

Gird up your loins, then, and enter the arena with determined purpose and honest ambition. In the words of Virgil, "Hic labor, hoc opus est;" the way to the solution of the problem must be found by your industry, your ingenuity, and your perseverance; in other words, by those qualities the combination of which is called genius. Did you ever hear of the solution by Darwin of the question as to the reason why clover grows so much more luxuriantly around human habitations than in places at a distance from them? Let me relate it to you as a good example of the method in which, by careful observation, by patient research, and by persevering labor, secrets hidden in the arcana of nature may be laid bare; as an illustration of the fact that truths in science are not stumbled upon hap-hazard, but are arrived at by working "line upon line, precept upon precept, here a little and there a little;" until the moment of fruition comes, and the investigator is rewarded by success. Such successes are called efforts of genius. But what is genius? The power of prolonged, undeviating fixation of thought; an absorbing mental devotion to the development of an idea; a "prolonged attention," as Sir William Hamilton tersely expresses it. Men phenomenally capable of such mental efforts live once in a century, not oftener. Socrates, Newton, Shakespeare, Napoleon, and Darwin mark the lapse of centuries in time as mile-stones mark the lapse of space. Oh, that Darwin had been a physician, and that he had stood on the night of his graduation just where you stand to-night! Oh, that among the gallant cohort of faithful men who face me now, more than one Darwin may be returning my glance!

But this is a digression. Let me return to the story of the clover. Clover is fructified by the transportation of pollen from male to female plants upon the legs of bees. Its petals are stiff, and thus the common bee is too light in weight to bend them apart and carry the pollen far enough down to accomplish the fructification of the plant. The heavy humble-bee only is capable of doing this. Now, the humble-bee lays its eggs just below the surface of the green sward, and here the field mouse devours them. Where cats exist field mice are kept from becoming numerous, the eggs are preserved, and thus it is that clover flourishes where man has his habitation and his companion the cat is present.

By just such reasoning has Metchnikoff, the bacteriologist, worked out his problems. Take, for example, his demonstration of the fact that the leucocytes of the green frog acted as phagocytes, or devourers, upon the bacilli of anthrax, to which that reptilian is invulnerable in a temperature less than 68° F. Filling a small sack made of the pith of a reed with anthrax bacilli, he put this under the skin of a green frog and sewed up the cutaneous incision. In a few days the lymph of the frog passing through the walls of and into the sack without leucocytes, the bacilli grew rapidly. Under the skin of the same frog, he at the same time inserted a piece of the spleen of an animal which had just died of anthrax. This he left unprotected by a sack. The leucocytes of the frog devoured the bacilli, and not one lived to perpetuate the disease. They acted as phagocytes, and Metchnikoff, by this simple and very ingenious experiment, proved that it was in this way that the frog was rendered invulnerable to this disease. At no distant period we shall probably see Metchnikoff cultivating thousands of the leucocytes of the green frog, inoculating with them other animals suffering from anthrax, and thus opposing one bacterial army by another, as Pasteur has already done.

Gentlemen of the graduating class, I have lauded to you the possibilities and the rewards of medicine; I have defined for you my conception of earthly reward; let me now test your sympathy with my views by putting to each of you in sober earnest this question: Which would you prefer to be—not during the insignificant period of two or three decades called your lifetime, but in that posthumous time which is called history—the soldier who, even in defence of his country and her supposed rights, has

won victories, filling households with sorrow, and inflicting the horrors of war upon a nation; or the man who has blotted out from the list of diseases that terror of the nursery, scarlet fever, which has in the past created, and is now creating, such havoc in our households?

Would you prefer to be the creator of that wonder of art, the Angelus, which for ages will continue to give real pleasure to thousands of people, or the man who for all time takes from his fellow travellers along the painful pathway of life, the terrible scourge called diphtheria? Would you prefer to receive the well-deserved rewards which have fallen to the greatest captain of our time, Von Moltke; or those which await Koch, if the cure of tuberculosis becomes practicable through his efforts?

The motto of the New York Academy of Medicine, coming down from mythological times, is this: "Homines deos accedunt, hominibus dando salutem." "Men most nearly resemble the gods, when they afford health to their fellow-men." If, as now seems highly probable, Robert Koch should succeed in curing and preventing tubercular disease in its various manifestations, what greater reward could he possibly ask for than the pleasure which he must feel when the reflection to which this motto gives rise comes to his mind? The reward of the physician whose happy discovery stamps out a disease which before his day slew its thousands, comes from the hand of no emperor; his glory from the appreciation of no applauding multitude; his renown from the pen of no fulsome historian. For him the victor's crown comes from the hand of the immortal God; his glory from the satisfaction of doing a great and glorious work; his renown from the gratitude of his fellow-men! The "great wakening light," which blessed the eyes of Abou Ben Adhem; not the imperial purple which decked the shoulders of the mighty Julius, constitutes his diadem and causes a halo to shine around his head!

In the golden days of chivalry, when a young knight was to receive the accolade and become the defender of the weak and the redressor of wrong, he was required to spend an entire night in a cathedral, or other solemn place, reflecting upon the purity, the beneficence, and the grandeur of his new office, and in forming the noble resolve to make it no trade, but to administer his duties with the love of man in his heart, and the glory of God in his soul. Let this night and these exercises bear to you the relation of that vigil night of old!

Medicine is the noblest of professions; the meanest of trades. Unless you can live lives of purity, of virtue, of honor, and of honesty, seek a livelihood elsewhere, and insult not the gods by striving through base methods and ignoble ambitions to resemble them!

Will you not now fully agree with me when, in closing this address, I ask you whether the possibilities of medicine are not really greater than those of her sister sciences and arts? Will you not accord in my postulate that arms, arts, literature, science, all have their rewards, but that not one of them surpasses in the magnificence of its gifts those of which the god-like science, Medicine, is capable?

When, a quarter of a century hence, I meet with one of you, as we both wend our ways along the highway of life, my locks as white as the driven snow, and yours as white as mine are now; come up to me, report yourself as a member of the graduating class of the Long Island College Hospital of 1891, and tell me which one of the beneficent discoveries, which the next twenty-five years are sure to bring forth, has been the means of causing you to resemble the gods and enrolled your name "among the few, the immortal names that were not born to die;" and I, recalling at once to mind you and this pleasant evening, which has made us acquaint, will bid you God speed, even as I do to-night.

Good for Mexico.—Mexico has nine medical schools in each of which the course of study is six years.

COUGH: ITS USES, SIGNIFICANCE, AND INDICATIONS.

By JAMES R. LEAMING, M.D.,
NEW YORK.

THE sound agrees with the sense. Cough is explosive and suggests forcing confined air through a passage. Its most obvious use is expulsion of mucus through the air-passages. Not so obvious, but equally important, is the expansion of the lungs. These two necessary conditions of health are maintained by this complicated automatic cough machine with which we also breathe. A deep inspiration is immediately followed by rigid contraction of the larynx to prevent the escape of the inspired air; and at the same time the diaphragm and intercostal muscles contract with all their power, secondarily assisted by the rigid contraction of the muscles of the abdomen and the perineum. At the supreme moment, when the contained air is most compressed, the muscles of the larynx give way and the tidal air is shot out, as from a gun-barrel, forcing out with it mucus, blood, or other foreign matter, producing the sound which gives it its name—cough.

There are two sources of stimulation which excite this act: 1st, that within the tidal air-tract; 2d, that within the pleuræ. The tidal air-tract is that part of the upper air-passages traversed by the air, in and out, in respiration, and is where air-friction is maximum. It is characterized by cartilage within the fibrous bronchial sheaths and the absence of alveoli. It is merely the passageway, and performs no other part in the office of aëration of the blood. The true respiratory system is characterized by the absence of cartilage within its passages, by the development of alveoli, and where air-friction is least. It is constantly distended by residual air, which is a barrier to the passage of inspired air in a body. "Two bodies cannot occupy the same space at the same time," is an axiom of physics, but the inspired air immediately mixes with the residual air by the law of diffusion of gases, and the distensible true respiratory system expands correspondingly.

Mucus, and in a degree pus and blood, occurring in the true respiratory system, are raised upward by the ciliary movement peculiar to the mucous membrane of this locality, until, reaching the tidal air, they are caught up and rushed out with an explosion. While this process is constantly going on in the upper air-passages of raising and expelling the mucus, at the same time, and by the same act, the residual air confined within the distensible true respiratory system is forced by the diaphragm upward against the lungs. The arrangement of air-sacs, terminal bronchi with their still more distensible alveoli, gathered into little bundles or lobulettes, and these into lobes forming the lungs, all covered in with pulmonary pleura only a little less distensible than what it contains, presents a system allowing great expansion without injury during the violent and repeated assaults of the diaphragm, but allows them to be dilated to their natural condition. The outer covering of the lungs, which keeps them in form and protects them from injury, is reflected upon the chest wall and forms a shut sac, the pleural cavity so-called, which is never a cavity except by pathological cause, but allows free movement of the lungs, and also furnishes a place for deposit for pathological products thrown out of the circulation. The blood of the body is brought to the lungs for aëration, oxygenation, purification. The residual air is filled with poisonous elements in gaseous form, derived from the venous blood, and were it not for the combustion constantly taking place in the lungs, the interchange of oxygen and carbon, their mutual attraction for each other as opposites and repulsion as similars, the life of the individual would at once come to an end. But purification takes place as by fire, and the separation of the poisonous gaseous elements on either side of the true respiratory line in the alveoli is maintained. Otherwise the exceeding tenuity of the membranes forming the

lungs would be no barrier to auto-infection from either side. But such elements as cannot be burned up and purified, or thrown out of the system by the natural emunctories, are extruded through the pleura and remain as a temporary deposit upon its surface, where, if nature is unable to remove it, or if it organizes into imperfect membrane, it immediately commences to contract, and shuts off in a degree the circulation in the capillaries of the periphery of the lungs. It may be but the beginning of simple fibroid, and its disabling effect only mechanical; again, it may be more mischievous, of a cancerous or tuberculous character, and its organization upon the pleura be but the beginning of active disease. Like the Mormons driven out of a healthy state organization into a territory, they there maintain a rival government with concentrated powers for evil, and they must be subdued, for they threaten the existence of the states. But the exudation upon the pleura is foreign, whether malign or benign, and excites cough while yet there may be no exudation of mucus. But in time the blood dammed up in the capillaries is back-watered into the nutrient arteries of the lungs, congests the bronchial arteries from which they are derived, and exudation of mucus or blood in the bronchial tubes is the natural relief; and this again excites cough: the cough of expulsion and the cough of expansion.

These facts in regard to the uses of cough are not enough considered. The popular demand is to stop the cough. But stopping the cough without removing the cause only increases the evil tendencies of the disease. There are other and successful ways of managing the cough than by overpowering the system with opiates.

About thirty years ago, Dr. George Philip Camman was elected a member of the New York Academy of Medicine and furnished his first paper, which, at his request, I read before the Academy. It was upon the management of cavities in the lungs by posture and position, in order to empty them, and thus to gain rest and sleep without giving large quantities of medicine. For instance, a patient coughs during the day when he is up and about, expectorating with relief. But at night, when seeking rest, he can lie but upon one side and then is kept awake with a teazing ineffectual cough. But if he attempts to turn upon the other side he is attacked with strangling and turns immediately back. Careful examination discovers a cavity with an opening in the roof, as considered in regard to the erect position of the patient, which, when he lies upon his left side, allows the contents to be discharged but partially, and consequently continually. But, by direction, turning over on the right side, and resolutely remaining there, discharges it completely and immediately. After which he can turn back upon the left side and sleep quietly until morning. The same principle may be carried out with a cavity, with a few exceptions, however situated in the lung or connected with a bronchus.

Mucous membranes of the air-passages, generally so sensitive, sometimes become tolerant to a wonderful degree. I have seen a man with an abscess in the pleura lying on his side, discharging pus through his mouth into a vessel, without cough.

A well-known former member of this Academy, and a visiting physician at Bellevue Hospital, had a superficial cavity in the right lung, in front, extending from the clavicle to the fourth rib. As soon as he began to move in the morning the cough commenced, and it was a struggle from that time on until it was emptied, which was at about two o'clock. He took an opiate in the morning, but it had no effect until after the cavity was emptied. The cough, strangling, vomiting, and disgusting nausea were painful to bear, and even to witness. Dr. Weir had just brought the first aspirator to St. Luke's Hospital, and I proposed to my friend and patient to draw off the contents each morning, but he declined it. The wall of the chest was the wall of the cavity, and a small Wyman's trocar and cannula would have been preferable to the aspirator. The cough performing its uses of expulsion or expansion should not be prevented. It should be guided so as to do its proper work without doing injury.

Whooping-cough is a self-limiting, self-protecting disease of infancy and childhood, and if uncomplicated forms no pathological products within the air-passages. The first few weeks is called the inflammatory period, in which the patient must be watched to prevent inflammation and dangerous complications. The cough must be modified and controlled, but not stopped.

The great use of this cough is in correcting the little disabilities which occur in infancy and childhood from colds and inflammations, or where portions of the lungs remain from birth undeveloped, as in atelectasis. There the whooping-cough becomes a powerful agent in expansion, and is a means of restoring the lungs to their normal state.

The disease appears to be mostly one of the pneumogastric nerve, and consequently the cough is characteristic. The irritating motive being located in the larynx, a succession of explosions ends in a long, noisy inspiration. But this is not always the case. I have seen a little member of a family of children all suffering with whooping-cough, who did not cough, but sneezed convulsively about as frequently as the others coughed—nearly every hour. He would feel the attack coming and brace himself to meet the inevitable, crying until it had passed. He had the same disease as the others, but the point of great irritation was removed from the larynx to the Schneiderian membrane.

I have seen a child who had been exposed with her playmates to whooping-cough, and while they coughed and whooped in regulation manner, she coughed, but only whooped in an undecided, doubtful manner, a few times; the disease running the usual time and getting well without pathological results in the lungs or air-passages.

We have already introduced the great pneumogastric nerve, or *par vagum*, as it is sometimes called, on account of its vagaries, for it goes everywhere.

In a well-appointed dwelling-house, in the proper place, will be found a little instrument to which wires running from every part of the house are attached, a bell, which rings and gives notice of the approach or interference of an enemy in the remotest part of the house. This is the ever-watchful burglar alarm.

The par vagum performs that and greater offices in the house of the soul, and its bell is constantly watchful. A pea put into the ear may cause cough or vomiting, hardened wax also. The cutting of a tooth may do the same. The air-passages and interpleural surfaces are the more direct avenues, and are the most obviously useful. Worms or indigestion are heralded with a cough. The kidneys and the liver telegraph, and announce the result with a cough. The reproductive organs have a peculiar sympathy with the par vagum, although perhaps no direct communication, unless it be through the great sympathetic.

Last summer I saw a young girl who came from a noted health-resort remarkable for altitude and dry, pure air, who was at a boarding-school. She had had in the spring what is called in her country mountain fever. She had recovered from it, but was chlorotic, and coughed hysterically incessantly. There were absolutely no pathological conditions to account for the cough. It was simply neurotic. I called it the hysterical cough of chlorosis. I recognize that, while not a frequent form of cough or of hysteria, it still occurs often enough and with peculiarities sufficient to be placed in a class. Since writing the above I saw in the London *Lancet* of December 20th last, "Remarks on the Barking Cough of Puberty," by Sir Andrew Clark, who has seen a large number of cases and has made a careful study of them, and gives a number in detail, boys and girls. We have many more such cases among girls, here, than among boys, for there appear to be peculiarities that are due to environments.

The American girl is bright, eager for knowledge, and is self-assertive. Her neurotic state will bring about more marked exhibitions of her peculiarities, not like her sis-

ter the English girl, nor the Continental. The English and Continental girls are not so soon developed mentally nor so demonstrative. The American boy is not like the ones described by Sir Andrew. They rarely have the barking cough of puberty. I do not remember to have seen one. The English boy, and especially in a minister's family, is repressed, private-secretary like, and will take on the barking cough of puberty when he is run down and made nervous. Both terms, the hysterical cough of chlorosis and the barking cough of puberty, might be used. Sir Andrew Clark states that he has seen about twenty cases, so that the disease is not frequent. Sir Morell Mackenzie reports one. One of Sir Andrew's could hardly be classed as pure neurosis, as he had dry râles and irregularity of the heart's action, and within the ten years which had elapsed since, had had two inflammatory attacks of bronchitis. But another case, a little girl whose cough drove everyone but her mother out of the house by its terribleness, was entirely cured by fright at the proposition to perform an operation upon her throat, displaying the instruments, etc., when she darted away and hid herself and was not found until late at night, and then her cough was gone. Entire proof of its neurotic character. I have an idea that I have seen other cases than the one I have reported, but I have no notes and can remember but one other which was well marked.

The par vagum is a chummy, friendly nerve. It is the source of all our friendships. We dine together, meet together, drink together, smoke together, by its influence. And in an assembly of people a cough will immediately be answered by coughs through the hall. One watching, too, who knows what he hears, will recognize the short hack of pathological conditions at the apices of the lungs; or it may be spasmodic, which indicates the lower part of the chest near the diaphragm as the location of the disease; or the cough may be simply catarrhal or nervous; or he may hear the scraping of the throat, the bringing up mucus with a rasping noise, which is a peculiar cough, and indicates old pleuritic adhesions relieved thus by a constant flow of mucus. Sometimes you may pick out of an audience several such, but whenever you hear this sign you may look for a thin, nervous, Cassius-like individual, "who thinks too much." For the scraping of the throat, the thin, anxious, worrying individual and old adhesions go together.

VALUE OF THE SUBCUTANEOUS ADMINISTRATION OF GOLD AND MANGANESE IN THE TREATMENT OF TUBERCULOSIS.[1]

By JOHN BLAKE WHITE, M.D.,

PHYSICIAN TO CHARITY HOSPITAL, ETC.

THE history of experimental pathology in relation to tubercle dates far back to the time of Laennec. The subsequent diligent researches of Cruveilhier and Erdt and Lombard added vastly to the stock of knowledge respecting the development of tubercle, but it was due to Klenke, and later to Lebert, of Breslau, and Villemin to first demonstrate the possibility of cultivating tubercle artificially by inoculation with opaque and transparent tubercular virus. I do not, however, propose to recapitulate the profoundly interesting advances made by that laborious galaxy of histologists who have successively added to our store of knowledge in relation to tuberculosis, until almost the culminating point of investigation appears to have been attained. It is enough at present to state that by far the most important doctrines in relation to tubercle and scrofula have been established by the experimental researches of the last twenty years.

The discoveries of Koch, within the last decade, have, indeed, opened up a new era in therapeutics. The future practice of medicine it would seem, must henceforth, in a great measure, be conducted by the hypodermic administration of remedies through that long-neglected avenue to the system, the absorbents. The special absorptive powers of the lymphatic system have been too clearly established, first by the illustrious Alexander Munro, in the beginning of the eighteenth century, and subsequently by John Hunter, to admit of any hesitancy on our part to trust at the present, its ready and beneficent co-operation.

Virchow has taught that the primary lesion in scrofulosis is simple hyperplasia within the glandular tissue. Shüppel has also proved that a scrofulous gland is indeed a tuberculous gland, and Friedländer has authoritatively asserted that the microscopic characters of lupus are identical with those of tubercle. In view, therefore, of such declarations from acknowledged men of science, taken together with the generally accepted opinion that the lymphatic system is especially prone to tubercular degeneration, I submit the inevitable conclusion, that the only true and direct route by which we may expect to antagonize such maladies must be through the skin and thus immediately into the avenues of the absorbent system.

When we desire to secure active and speedy effect of a remedy we must have recourse to the hypodermic method. We cannot fail to admit that remedies introduced by the mouth to antagonize diseases originating in the glandular system are subjected to too great dilution and chemical change in their course before they reach the seat of lesion to expect the advantage that surely would accrue if introduced more directly into the circulation by the subcutaneous route.

Taught by recent experiences, the wise physician of the present day must recognize the fact that the numerous elements of our materia medica known to possess power of antagonizing disease have heretofore failed, owing rather to error in their mode of administration than to deficiency of virtue or potency in the drug itself.

The powers of an ill stomach may well be spared the incongruous task forced upon it of distributing drugs to distant morbid conditions and assimilating nourishment for the support of the body.

Even though the intimate composition of the lymph of Professor Koch be destined to remain a secret from the profession he so greatly adorns, medical men throughout the world must ever be profoundly grateful for the new direction his genius has opened in the practice of medicine.

Functional incapacity of the organs of digestion and assimilation is the first evidence presented to us of tubercular invasion, which is manifested by absorption of the adipose tissue and by muscular atrophy—depending upon faulty nutrition. Such condition, as we are all aware, is followed by listlessness and low vitality, which lessens respiratory vigor, favoring the accumulation of mucus in the air-cells and bronchi that in turn excites inflammation, and so becomes the nidus of inimical bacilli. Dr. Sibson very aptly and truly says, that not only life depends on respiration, but vital energy is in a great measure governed by the freedom and capacity of the respiratory organs. It is not a difficult matter to appreciate this when we contemplate how dependent is the condition of the blood upon the aeration afforded through the medium of the lungs, and that whatever impedes or interferes with thorough oxygenation of this vital fluid must favor physical decay, for the prime condition of phthisis is impurity of the vitalizing current.

It will be therefore seen how important a matter lung exercise becomes, not only to those subject to pulmonary disease but also to the healthy and strong. The less these organs are used and expanded the more useless they become, as has been so forcibly dwelt upon by our own distinguished authority, Dr. James R. Leaming, and present a ready recipient of micro-organisms, while the more their full capacity is encouraged the more is their vitality established.

The apices of the lungs are the first tracts to break

[1] Read before the Section of General Medicine, New York Academy of Medicine, February 17, 1891; also, by special invitation, before the New York Medical Union, March 10, 1891.

down, because, as is generally supposed, there is less expansion of this portion in the ordinary respiratory act, and this passive state especially favors tubercular inception and degeneration.

The early detection of lesion is not an easy matter, but requires frequent critical observations extending over long intervals of time to be discerned, for morbid processes in the lungs are very insidious, creeping along almost imperceptibly, until, in the language of Aitken, "day by day, and grain by grain the mortal part wastes and dies away." Aitken declares that one of the best indications of advancing tuberculosis is gradual but continuous loss in weight, or, more properly speaking, a deficiency in the ratio of weight to age, height, and respiratory and other functions. There is no doubt of this in my own mind, the difficulty being in fixing this ratio, which, however, is quite practicable. It has been my practice to estimate in all cases the respiratory capacity and to base my prognosis, in many instances, largely upon the data thus obtained. If I find the respiratory capacity progressively lessened while a patient remains under observation, I have been led to regard the prospects of advancing tuberculosis very probable, especially if associated with this condition is found progressive failure of nutrition.

There is an undoubted period preceding the deposit of tubercle in which the blood becomes impoverished through faulty digestion and assimilation. This is the stage described by some authors (E. Smith and others) as the pretubercular; and as it precedes the deposition of tuberculous matter we cannot afford to wait for the actual detection of the tubercle bacilli before a diagnosis is made and a proper line of treatment determined upon.

The observations of Dr. Bennett, of Edinburgh, confirmed by many others, tend to prove that treatment simply aimed to correct malassimilation of food not infrequently arrests the tubercular process and causes the complete disappearance of all general symptoms, as well as physical signs of tubercular degeneration.

The dictum uttered by Cullen is sound to-day, that "beyond a certain degree of emaciation and debility no man recovers." The first and most important indication in the treatment of tuberculosis should be to attempt to re-establish functional activity of the organs most directly concerned in the nutrition, since under the tuberculous influence the vital forces perniciously wane.

Dr. R. C. M. Page[1] declares that true tubercle does not always contain the bacillus, but that true tuberculous virus free from Koch's bacilli is capable, by inoculation, of reproducing itself; which is in accord with other observers, and explains the absence of the bacillus in true tubercle when sought for by its non-liberation, the germ only existing.

Here we have suggested the relation of the bacilli to tuberculosis, which the majority of physicians to-day regard as settled by the deservedly renowned Teuton. As it has been well established by equally high authority that we do have a fixed tubercular state prior to deposition of tubercle, with no bacilli discoverable in the sputum, and as the establishment of tubercular tissue, according to Koch himself, is a necessary condition to enable the micro-organisms to flourish, we are yet unable to reconcile our minds to a full acceptance of the doctrine that the tubercle bacilli are the direct causes of tuberculosis.

We have always considered that they were potent factors in the continuation of the process, after finding a suitable nidus in which to propagate, but not until such condition has been established will a search for the microbe be successful. The discussion of this subject, however, is not a part of this paper, but has been merely alluded to thus far for the purpose of approaching, rationally, the line of treatment to be hereinafter detailed.

For years past pulmonary tuberculosis has been successfully treated by judicious administration of medicines and the institution of hygienic measures in the incipient stages. Cases have also been recorded of well-advanced tubercular processes which have yielded to simple methods of treatment.

To produce a physical condition not favorable to the deposition of tubercular tissue, and therefore inimical to the intrusion and germination of microbic life, has been the ordinary course of treatment long before the bacilli were discovered by Koch. The same line of treatment is even now advised by the distinguished bacteriologist himself, who states that his famous lymph has not the power to destroy the microbe, but that it has selective action in its direction to the tubercular tissue, causing it to be thrown off and leave a condition of tissue vitality which proves an effectual barrier to bacterial invasion and multiplication. This must not only be due to selective action of the lymph itself but to some somatic change effected through the agency of some of its elements, which results in a restoration of functional activity followed by an improvement in general nutrition.

We have in the materia medica remedies that have long been known to possess this particular power, but none in so direct and potent a degree as the preparations of gold, which, from no fault of their own, have long since fallen into desuetude. The precise action of the preparations of gold upon the system is not yet fully determined, but there is ample reason for the belief that they exert a remarkable influence upon the general nutrition. I therefore especially refrain from making, with regard to my own fluid, the mysterious assertion that it might be used in the diagnosis of disease. I think I can venture, however, to assert, and enforce the assertion with reason, that the remedy acts upon diseased conditions with such natural promptitude, being introduced in a pure chemical state directly into the circulation through the absorbents, that in its mode of action it presents all the appearance of an alert detective upon the track of an offender.

The precise mode of action of no element of the materia medica is distinctly understood. That certain medicines do manifest their peculiar virtues upon particular organs of the body has long been an undisputed fact. Why and how Ipecac expends its first effect upon the stomach, Strychnia upon the spine, and Digitalis upon the heart are questions that have never yet been answered. But that any drug is endowed with the faculty to discover and pursue a morbid lesion within the body at large is a new doctrine which, in the present state of our knowledge, we are unprepared to admit. Let us, then, not pretend to claim that this or any other remedy is endowed with the occult and extraordinary faculty to first discover, then pursue existing lesions not yet discerned and located by our own acumen.

I will now proceed to detail candidly the views entertained by high authorities respecting this remedy, being convinced that most of these opinions are true in some particulars, and that the absolute truth will be found in a comprehension of all opinions. From this aggregated testimony the conclusion must certainly be arrived at that the various preparations of gold possess rare and active therapeutic qualities, and in the hands of only the unskilled are likely to occasion other than benefit. The administration of gold in phthisis dates back even to Paracelsus, and up to the times of Horst and Poterius gold in combination with bichloride of mercury was depended on in the treatment of the various cachexias resulting from phthisis, scrofulosis, syphilis, etc.

The violent effects of the remedy in the hands of bold experimenters, however, soon brought discredit upon it, and it is not improbable also that many adulterated preparations were used, which accounted for the subsequent loss of confidence in this remarkable remedy.

The preparations of gold had long been neglected when Christien,[1] in 1810, again brought them into notice and caused their eminent therapeutic value to be fully recognized. He esteemed the chloride to be by far the most active and reliable in its effects, and extolled its efficacy

[1] MEDICAL RECORD, October 13, 1888.

[1] Recherches et observations sur les effets des préparations d'or.

chiefly in the treatment of lympathic degenerations and the cachexias resulting from phthisis, syphilis, and scrofula.

Hoffmann claimed that he obtained from its use entire success in the treatment of cancer of the plyorus and cancer of the uterus. A marked value has been claimed for this particular salt by Hufeland, Herrmann, Riecke, Meisner, Grotzner, Gozzi,[1] Krimer, and Delafield, in dropsies dependent on organic disease of some important viscus. According to Carron du Villards the catamenia is influenced as to frequency of recurrence and quantity by moderate doses of the chloride of gold. Though recommending to favor all preparations of gold M. Pourché[2] rather relied upon the cyanide, which he considered milder in its action than the double chloride and yet quite adequate to fulfil all the specific effects required in the treatment of disease. Pitcairn and Neligan [3] both assert that the chloride of gold, while indentical in its effects with mercury, appeared to exert a more decided influence on chronic syphilis.

The potent efficacy of the gold preparations in syphilis, scrofula, phthisis, tumors of the bones, scirrhous indurations, especially of the tongue, and glandular enlargements have been emphatically dwelt upon by such undoubted authorities as Neil, Cullerier,[4] Mitchill,[5] Biett, Lallemand,[6] Wendt,[7] Le Grand,[8] Eberle, and Kopp.

Magendie [9] declared his belief that the cyanuret of gold promotes coagulation of the blood. When, therefore, a decided modification in this fluid is desired in hemorrhages or in chronic affections, its administration may prove of great value.

M. Chavannes [10] has found the chloride of gold to be a remedy of rare virtue when applied externally as a caustic in lupus, syphilitic tubercles, and ulcers.

Orfila [11] affirms that the chloride of gold is more active than corrosive sublimate, and that when administered in doses of $\frac{1}{20}$ to $\frac{1}{10}$ of a grain it will give rise to more or less inflammation of the gastro-intestinal mucous membrane. Experiments instituted by him upon dogs go to prove that even when a very small amount of this preparation of gold in solution is injected into the jugular vein death will speedily ensue by vomiting and suffocation, preceded by a short paroxysmal cough.

In his experiments upon mammals with the chloride of gold, T. Lauder Brunton [12] found that small doses encouraged the appetite, while large doses started symptoms of irritation of the stomach and intestinal canal together with a pseudo catarrhal condition of the respiratory passages resulting in death by asphyxia. When large doses were injected into the veins œdema of the lungs occurred and death rapidly followed, with convulsions and asphyxia.

No authority, perhaps, ever devoted more careful research into the physiological action of the gold preparations than the justly renowned Aronowitsch. Conducting his experiments with a dilute solution of the double chloride of gold and sodium and also another solution of a triple salt composed of gold, sodium, and sulphur, he found that in cold-blooded animals both preparations caused central paralysis, the respiratory function being affected before that of the heart or brain. In warm blooded animals even long-continued small doses produced no very marked effect, the animals maintaining a good physical condition and even gaining in weight. When the dose was increased, the appetite failed, followed by progressive emaciation, acceleration of the pulse, excitation of the respiration, and decrease in animal heat. When 0.3 to 0.5 gm. of the chloride of gold was introduced under the skin there was great unrest, the pulse became quickened and an exhausting diarrhœa commenced. No more being administered spontaneous recovery advanced in less than three or four hours. After the administration of 1.0 gm. to a fresh subject the same symptoms manifested themselves but with overpowering intensity, destroying the animal in less than an hour after causing decline of temperature with convulsions and arrest of respiration. The post-mortem examination revealed most prominently pulmonary œdema.

Bartholow,[1] while greatly extolling the efficacy of the gold preparations in cancer, scrofula, constitutional syphilis, and in chronic Bright's disease, advances the important observation that they are singularly apt to undergo decomposition in the alimentary canal, a part only being absorbed as an oxide in combination with albumen. This fact would explain, in many instances, the inefficacy of the remedy when used internally, and is the strongest plea that could be advanced for the more direct or hypodermic method of obtaining its effects in the system.

All these authorities, however, concur in stating that the remedy, so potent for ill when pushed to toxic effect, exhibits rare eutrophic virtues when administered in strictly therapeutic doses.

Under prolonged use of the preparations of gold an auric ptyalism may occur, but the salivation thus produced never assumes the same profuse and debilitating character as that superinduced by mercury or iodine.

I have met with one individual in my experience who manifested a peculiar idiosyncrasy against tolerance of chloride of gold. Her pulse and temperature fell below normal four hours after the administration, hypodermically, of a minimum dose, and, without presenting any other symptom worthy of note, these phenomena continued for two or three days. But mark the sequel; after the pulse and the temperature had returned to their natural grade I subjected her to treatment with Koch's lymph and to my astonishment I found her again presenting the identical symptoms above described, which endured about the same length of time. Five minims of a one per cent. solution of carbolic acid was injected also by House Surgeon Dr. Newman without causing the same phenomena.

I believe that the value of gold as a therapeutic agent, especially in phthisis, is enhanced by the addition of the iodide of manganese. This latter ingredient is itself an influential tonic and anti-anæmic, and has long and justly been regarded as on a par with, if not superior to, the preparations of iron. It is an element ever present in the blood as well as in the other fluids and solids of the body, and is certainly better tolerated than iron when administered to remedy the persistent anæmia of tuberculosis.

Under the influence of these combined salts in the manner advised the very action which Garrod hoped to achieve by the salts of potash seems singularly secured, viz.: "a ready metamorphosis of the less vital tissues, less vital deposits, less vital plasma, and of course of the deposition forming the glandular and other swellings of scrofula."

Mr. Hannon tried the carbonate of manganese upon himself. After taking it for several days he observed that his appetite had increased, that a decided tone had been given to his circulation and that the functions generally had been aroused to a more healthy action. He further experimented with it in cases of syphilitic cachexy, phthisis, scrofula, and cancer, and noticed that in every instance the quality of the blood had undergone very marked improvement.

The effects obtained in my own experience with the particular combination I am in the habit of using, hypodermically, have been first exhilarant, followed by an increase in animal heat and vital activity. The pulse becomes more full and active, the temperature rises and a

decided period of reaction is established. During this period a constriction about the chest is sometimes complained of, amounting in certain cases to absolute dyspnœa. This sooner or later is followed by depression more or less expressed, which never lasts long. These are commonly succeeded by the more permanent tonic and alterative effects manifested by remarkable increase in appetite and weight, with marked amelioration of the various morbid symptoms.

In a few cases presenting idiosyncrasy there resulted, after an ordinary dose, chill and subnormal temperature with headache. In such cases it is unnecessary to advise caution in repeating the dose, as the propriety of refraining must be at once apparent.

The initial dose of the fluid should not exceed one drop for adults, but may be increased to three drops provided no intense reaction has been produced by the tentative doses. When three drops were administered as an initial dose certain cases manifested dyspnœa, increased cough with bloody sputum. These, however, disappeared entirely within twelve hours, followed by the usual exhilarant effect, with amelioration of cough and expectoration.

I have found these salts combined administered hypodermically very efficacious also in the chronic glandular enlargements and sinuous abscesses due to scrofula, chronic obstinate skin affections, especially of a leprous character, persistent anæmias, chronic Bright's disease and the cachexias due to syphilis and scrofula.

For using the fluid, the following directions are to be regarded: Take from five to ten minims of a one per cent. solution of carbolic acid and boil it in a test-tube. (This step is unnecessary if a one per cent. solution of carbolic acid is prepared with distilled water.) When thoroughly cooled, add one or two drops of the fluid (the dose intended for injection), and when well mixed charge the syringe for use. The patient's temperature should be carefully recorded every three or four hours, and no dose should be repeated until the reactionary effects of the previous dose have subsided. It is suggested that the patient's temperature be noted every four hours for several days before treatment is commenced. The remedies introduced hypodermically sometimes produce powerful effects in individual instances, therefore great caution and judgment are to be exercised in their administration. For this reason the initial dose should never exceed one drop for an adult.

In combining the chloride of gold and sodium with the iodide of manganese, unless some special skill is exercised, a precipitate always results which it is very necessary to avoid, because it will be found to depreciate the value of the liquid and may even render it useless.

When correctly compounded it should have no precipitate, and present a rich, transparent, garnet color, as the specimens herewith exhibited.

Thus far it has been prepared in accordance with my directions by Messrs. C. F. Lord, 482 Seventh Avenue, and W. E. Cramer, corner of Park Avenue and Seventy-third Street.

Without taking up more of your time, or fatiguing you with the details of the various cases which have been subjected to the treatment, I will only record a few which have shown characteristic temperature reactions, and otherwise exhibited symptoms of interest, with decided evidences, in individual instances, of benefit from the treatment.

In all but one of the cases reported the diagnosis has been corroborated by the determination of the presence of tubercle bacilli in the sputum, and all manifested physical signs of more or less advanced phthisis. The cases were not selected, but taken as they presented and expressed readiness to receive the treatment.

I desire to express my appreciation of the aid afforded me by my associate, Dr. Charles Lewis Allen, in the observation and care of my private patients, as well as the assistance rendered me in the hospital by my able staff, Drs. J. H. Coughlin, C. J. Proben, and H. S. Goodall.

Case I.—Mr. J. F——, private patient, aged twenty-three, single; collector. Father and brother died of pulmonary tuberculosis. Up to two years ago was perfectly well. At this time took cold and began to cough and expectorate, and with loss of appetite lost flesh rapidly. Indications of tubercular invasion were manifest in both lungs, but the right apex was especially affected. On auscultation loud mucous râles were heard, anteriorly in infra-clavicular region, with few moist fine râles extending down to base of chest, and pleuritic friction-sound subaxillary and posterior aspects of right chest. Under appropriate treatment—inhalations, tonics, etc.—an improvement resulted, but more or less cough with slight expectoration continued.

February 1, 1891: The cough becoming more aggravated, the resulting increase of expectoration and losing appetite and flesh induced him to consult me again. He has been coughing and expectorating a muco-purulent sputa for past six months. Sputum was examined by Dr. Charles Lewis Allen and found to contain bacilli of tuberculosis, which he kindly demonstrated to me.

Physical Examination.—Right lung: Diminished expansion, dulness on percussion anteriorly and posteriorly, extending down to middle lobe. Modified percussion note over lower lobe anteriorly, but dull posteriorly. Moist râles discerned anteriorly, upper portion of lung louder, mucous râles extending down to base with increased fremitus. Posteriorly fremitus increased all over the right lung, and some moist and dry râles discerned. Left lung: Percussion sound modified slightly; broncho-respiratory murmur feeble anteriorly and posteriorly. Some loose râles heard over middle portion of chest. Has some irritation in throat and a feeling of tightness across chest. Body weight, 135 pounds.

First injection, February 1, 1891. Temperature, 98.5° F., 6.30 P.M.; injected 1 drop. I was not able to follow the temperature curve in this case, as he lives some distance from me, but the patient informed me that he felt feverish after the injection.

February 5th. 6.30 P.M.: Temperature, 98.5° F.; injected 2 drops.

February 10th. 7 P.M.: Temperature, 98.5° F.; injected 2 drops. Cough and expectoration diminished and appetite much improved.

February 13th. 7 P.M.: Temperature, 98.5° F.; injected 2 drops.

February 16th. 6.45 P.M.: Temperature, 98.5° F.; injected 2 drops.

February 19th. 6.45 P.M.: Temperature, 98.5° F.; injected 2 drops. All cough and expectoration ceased, no irritation in throat.

February 24th. 6.45 P.M.: Temperature, 98.5° F.; injected 2 drops.

February 26th. 6.45 P.M.: Temperature, 98.5° F.; injected 2 drops. Feels quite well and strong and has no cough or expectoration. Body weight, 135½ pounds.

This patient while under the above treatment received no other medication. His general physical condition markedly improved, cough and expectoration checked. Leading a very active life it is not remarkable that the body-weight showed no greater difference than at the beginning of treatment. The evidences of general amelioration, however, are especially worthy of note. I have desired sputum for microscopic examination, but have been assured that none can be obtained.

Case II.—Miss S——, private patient, aged twenty-one; native of the United States. Began treatment January 11, 1891. Father, brother, and sister died of pulmonary tuberculosis. A year ago began to cough and expectorate a frothy mucoid sputa; throat felt sore and voice was hoarse. Upon examination found percussion-note modified over upper portion of right lung anteriorly, and auscultation revealed harsh bronchial breathing, with few coarse moist râles. For the past year has been much annoyed with irritation and tickling in the pharynx and larynx. Laryngeal examination showed slight œdema of

vocal cords and mucous surfaces about the glottis. Body weight, 120 pounds

January 11th: Temperature, 99° F.; injected 1 drop.

January 15th. 3 P.M.: She said she felt feverish during the evening after last injection. Had slight headache. Cough increased, with a little bloody expectoration. Irritation in throat lessened and had better appetite. Temperature, 99.4° F.; pulse, 94; injected 1 drop.

January 18th. 3 P.M.: Twenty-four hours after last injection, increased cough with bloody expectoration. Cough this day much less. Appetite much increased. Much less throat irritation. Temperature, 98.5° F.; pulse, 86; injected 1 drop.

January 20th. P.M.: No more bloody sputa. General improvement reached. Temperature, 100° F.; pulse, 84; 3 P.M., injected 1 drop. Weight, 121½ pounds.

January 23d. 6 P.M.: After last injection, January 22d, had a little bloody expectoration and felt somewhat feverish during the afternoon. Temperature, 99.6° F.; pulse, 84; injected 2 drops.

January 25th. P.M.: Cough less. Temperature, 98.5° F.; pulse, 80; injected 2 drops.

January 29th. P.M.: Cough decidedly diminished and little expectoration. Catamenia recurred at this time, and the flow was increased. Temperature, 98.8° F.; pulse, 94; injected 2 drops.

February 1st. P.M.: Feels much stronger, and in every respect is better. Temperature, 99.4° F.; pulse, 100; injected 2 drops.

February 5th. P.M.: Temperature, 98.5° F.; pulse, 84; injected 2 drops.

February 8th. P.M.: Temperature, 98.5° F.; pulse, 84; injected 2 drops.

February 12th. P.M.: Temperature, 98.5° F.; pulse, 80; injected 2 drops.

February 15th. P.M.: Temperature, 98.5° F.; pulse, 72; injected 2 drops. Weight, 122 pounds.

February 17th. P.M.: Temperature, 89.2° F.; pulse, 82; injected 2 drops. Cough and expectoration nil, and throat relieved.

February 22d. P.M.: Temperature, 98.5° F.; pulse, 88; injected 2 drops.

February 27th. P.M.: Temperature, 98.5° F.; pulse, 80; injected 1 drop.

March 2d. P.M.: Temperature, 98.5° F.; pulse, 78; injected 1 drop. Weight, 122½ pounds.

No other medication received. Though no bacilli were discoverable in the sputum, I am quite satisfied that the case was one of undoubted pulmonary tuberculosis in its early stage.

CASE III. *Phthisis Pulmonalis; Albuminuria.* — J. E——, male, aged twenty-five; United States, single; wood planer. Admitted to hospital November 18, 1890. Father died of consumption; also a sister, niece, and nephew. For the last twelve years has had more or less cough following an attack of pneumonia. Cough is particularly severe in the morning. Expectorates a large amount of muco-purulent sputa, which on microscopic examination was found to contain tubercle bacilli. At times the cough is so paroxysmal in character that it often gives rise to emesis. Has frequent attacks of diarrhœa, sweating at night, no appetite, and has gradually been losing flesh and strength. Since he began to cough has had hæmoptysis two or three times. In the afternoon and evening has fever and complains of pain over both lungs, extending through to the back, pain increased on full inspiration. Physical examination: Expansion of chest on both sides diminished, with retraction of chest in the infra-clavicular and supra-clavicular regions of both sides, more marked, however, on the right. Vocal fremitus increased on the right side. Left chest anteriorly: Dulness on percussion marked posteriorly. Modified percussion sound over middle or subscapular region. Auscultation revealed loud moist râles in the infra-clavicular region of both lungs, with feeble bronchial respiration. Posteriorly, upper portion of left lung, moist râles with feeble broncho-respiratory murmur. Over lower lobe the respiratory murmur clearer, but a few coarse and fine moist râles were discerned. On the right side, posteriorly, feeble respiration with some mucous râles, especially heard at the base. Evidences of pleuritic adhesions discerned posteriorly in subscapular region along spinal aspect of both chest-walls.

The local disease has not proceeded to a very advanced stage, though softening of the tubercular exudation at the apex of the left lung was clearly discerned. This patient gave evidence of debility, some emaciation, with distressing cough, night-sweats, profuse expectoration, anorexia, and albuminuria, with granular and hyaline casts. Quantity of urine passed in twenty-four hours was 135 ounces. First injection of 1 drop of the gold and manganese fluid was administered December 24, 1890, about 4 P.M. Body weight, 116 pounds. Temperature, 99.2° F.; pulse, 108; respiration, 28. About 6.30 P.M., he complained of a sense of constriction about the chest with some dyspnœa, which soon spontaneously disappeared. The temperature rose to 100.4° F., and afterward gradually declined to normal, not exceeding 99° F., the following day.

On December 27th the quantity of urine passed was 125 ounces in twenty-four hours. At 5 P.M. 2 drops of the fluid was administered, the patient's temperature being 98.4° F.; pulse, 76, and respiration, 28. No record was kept of the temperature after this until the next day, but the curve did not extend above 99.2° F.

December 29th, P.M: Two drops were again administered, the temperature subsequently rising to 101.2° F.; pulse, 120; respiration, 36; and the excretion of urine again increased to 135 ounces per day.

December 30th: The temperature did not exceed 99.4° F.

December 31st: The highest temperature curve, being 99.4° F., and not exceeding this until 4 P.M. January 4th, 1891, when it reached 100° F. An injection was administered January 2d, but no reaction followed.

January 5th: Another injection was given of 2 drops, the temperature rising to 99.8° F., receding to 98.5° F., and rising the following day to 100.7° F., after which it gradually declined to normal. Body weight, 119 pounds.

January 7th: Injected 2 drops of the fluid, the temperature again rising to 100° F. Excretion of urine, 104 ounces a day.

January 9th: Injected 2 drops 10 A.M., reactionary fever not over 99.5° F. Cough and expectoration diminished.

January 11th: Injected 2 drops, followed by slight reaction. Temperature, 99.8° F.; pulse, 92; respiration, 32.

January 14th: Body weight increased to 120 pounds, and urine excreted not more than 86 ounces.

January 18th: An injection of 2 drops was followed by no fever; pulse rate, 78 to 84, and respiration, 32.

January 23d. Two drops were injected, causing a temperature of 100.7° F., and on the morning of the 24th the cuvre reached 102° F., gradually declining. The quantity of urine excreted about this time was 66 ounces per day. From this time on to February 12th the injection of 1½ drop was administered every other day, causing no elevation of temperature above 99.5° F.; the excretion of urine not exceeding 60 ounces, and body weight reached 124 pounds. The patient's general physical condition is markedly better. Has little cough and expectoration. Appetite excellent, and manifests every evidence of amelioration of his disease. Latest body weight, 125½ pounds, being a gain in weight of 9½ pounds to February 20th. Urine examined February 27th by Drs. R. H. Pomeroy, P. Meirowitz, and A. Rosenthal, of the house staff. Barely a trace of albumin, and no casts found under the microscope. The prompt amelioration of the nephritic symptoms in this case is no less remarkable than the benefit which the patient experienced from the injections in respect to his pulmonary and general physical condition.

Case IV. *Phthisis Pulmonalis; Albuminuria.*—W. D——, aged thirty; Ireland; single; stableman; admitted to hospital November 26, 1890. Family history negative. Twelve months ago was quite ill and had a severe cough with hæmoptysis resulting from a thorough wetting and going to sleep in his wet clothes. Cough always more severe at night and in the morning, when he expectorates a large amount of muco-purulent matter. Has lost much flesh, and strength much reduced. Sputum shows the presence of bacilli. Albumin, with casts, in the urine.

Physical Examination.—Emaciation. Expansion lessened on both sides, with marked infra clavicular depression. Fremitus increased over both apices. Percussion dull over left apical portion anteriorly. Modified percussion-sound in subaxillary portion and in subscapular region. Right side: Exaggerated resonance in infra clavicular region as far down as third rib, posteriorly, and in subaxillary space marked dulness on percussion. Auscultation: Broncho cavernous respiration right apex and infra-clavicular portion of lung, with loud gurgling crepitation as far down as third intercostal space. Coarse moist râles also heard anteriorly and posteriorly over right lower lobe. Left side, anteriorly loud moist râles and bronchial respiration extending down to base and a similar condition heard posteriorly, with some subcrepitant rhonchi. First injection of 1 drop gold and manganese liquid was administered December 26, 1890. Body weight, 113 pounds. Urine excreted per diem, about 55 ounces. The temperature at the time of the injection was normal; there was only a slight reaction to 99.2° F.

December 29th: Two drops were injected, followed by a reaction to 100° F., which subsequently decreased to normal. The amount of urine excreted was increased after the two injections to 65 ounces.

An injection of 2 drops was administered January 2, 1891, followed by reaction to 99.8° F., and on January 4th, temperature, 99.2° F., after the injection; the quantity of urine excreted about these dates amounting to 82 ounces in twenty-four hours. Injections of 2 drops gold and manganese liquid were given January 6th, followed by rise of temperature to 100.2° F.; January 8th, with temperature curve 100.6°; January 9th, with a reaction of 100.4°; January 11th, 99°. All of these injections were administered when the temperature was about normal, or not exceeding 99° F. The body weight January 5th was 111 pounds, and on January 14th 112 pounds. The urine excreted at this time did not exceed 44 ounces a day.

Injections of 1½ drop were given January 13th, 15th, 18th, and 21st. No reaction of any note resulted till after the last injection, when the temperature became elevated to 101.8° F. On this date the body weight had increased to 114 pounds, and the patient declared his cough and expectoration was lessened and his appetite much improved. The excretory function of the kidneys was stimulated again so that about 64 ounces of urine were passed in twenty-four hours.

January 23d: One and a half drop was again injected, the patient's temperature being normal at the time, and a reaction to 100° F. followed, subsequently declining to normal and again rising to 99.4° F. after injections of same dose January 25th and 27th. On the 29th the temperature was 99° F. at the time of an injection of 1½ drop, and four hours after there was a reaction to 100° F. Excretion of urine on this date was 32 ounces per day. Body weight, 115 pounds.

February 1st: Injection of 1½ drop. Temperature rose from 98.8 F. to 101.6 F.

February 3d, 5th, and 7th the injections were continued, followed by no marked reaction. Body weight increased to 119 pounds, with pulse, 84; respiration, 28; and evidences of general amelioration of his condition quite manifest. Cough and expectoration much reduced.

February 11th: Body weight increased to 121 pounds. Urine now free from albumin and casts, and amount excreted in twenty-four hours averaging 55 ounces. The gain in weight of this patient was from 113 to 123 pounds in ten weeks' treatment.

Case V. *Phthisis Pulmonalis.*—Patrick McC——, aged twenty-nine; single; United States; driver. Admitted to hospital November 24, 1890. Family history: Father died of pneumonia. In March, 1890, had hæmoptysis, followed by cough, night sweats, and loss of flesh and strength. Dry pleurisy in August. Now has poor appetite and sleeps badly on account of cough and sweating. Sputum discoid and muco-purulent, and contains bacilli. Physicial examination shows consolidation at both apices, more marked on right side, with moist râles over both upper lobes.

Treatment was begun on January 9, 1891, at 10 A.M., by an injection of 2 drops of the gold and manganese solution. Patient's highest temperature, 100° F.; pulse, 88; respiration, 30. Body weight, 129 pounds. Temperature had commenced to rise at 12 M. (100.4° F.), and reached 102° F.; pulse, 96; respiration, 40, at 4 P.M., after which they gradually declined.

January 10th: An afternoon rise, reaching 102.6° F.; pulse, 96; respiration, 48 at 8 P.M.

January 11th. 10 A.M.: Injection 2 drops. Temperature, 100° F.; pulse, 104; respiration, 44. Temperature rose by 4 P.M. to 101° F., then declined. No accurate record of temperatures was kept again until January 20th.

January 15th: Patient received injection of 2 drops, and January 17th of 1½ drop. The quantity of urine, which had been heretofore between 30 and 40 ounces per diem, increased on January 20th to 84 ounces.

January 20th. 2 P.M.: Injection, 1½ drop. Temperature did not go above 99° F.

January 21st: Temperature commenced to rise by 10 A.M., and at 4 P.M. had reached 101.8° F. (pulse, 120; respiration, 40), then gradually declined. Body weight, 128 pounds.

January 22d: Similar rise of temperature occurred, commencing A.M., height reached at 6 P.M. 101.4 F.

January 23d: Similar curve. At 2 P.M. injection 1½ drop. Temperature, 101.2° F. at 2 P.M. Kept up until 6 P.M. From this time to February 4th the temperature range remained similar, being from normal to 100° F. in the morning, and rising to 101° to 101.4 F. between 4 and 8 P.M., whether injections were given or not.

Injections of 2 drops were given January 25th, January 27th, January 29th, February 1st, February 3d. The quantity of urine had decreased on January 27th to 48 ounces, and remained diminished at about that quantity. On January 30th the patient's weight was 127 pounds and he was sweating a great deal at night.

Patient subsequently left the hospital. Body weight being same as at first, 129 pounds.

Case VI. *Phthisis Pulmonalis.*—Owen B——, aged thirty; single; stableman. Admitted December 26, 1890. Family history negative. Health good until eight weeks ago, when he began to cough and shortly afterward to expectorate muco-pus containing tubercle bacilli. Sweats at night. Has lost flesh and strength and has poor appetite and pains in chest. Physical examination shows signs of consolidation at right apex, with pleuritic friction-sounds and râles diffused throughout right lung. Treatment was commenced on December 27, 1890. His weight at this time was 126 pounds. Temperature at 5 P.M., 99° F.; pulse, 100; respiration, 32; at which time an injection of 2 drops of the gold and manganese solution was given. At 9 P.M. his temperature was 101° F.; pulse, 92; respiration, 36.

December 28th. 5 P.M.: Highest temperature, 99.2 F.

December 29th. 3 P.M.: Injection of 2 drops. Temperature at that hour, 100.2 F. At 7 P.M. it had reached 101.8° F.; from which it slowly declined.

December 30th. 10 A.M.: Highest temperature, 100.6 F.; declining to 99.6° F. at 2 P.M. and rising again to 100.2° F. at 7 P.M.

December 31st: 5 P.M.: Injection of 2 drops. At 7

P.M., temperature, 101° F., remaining stationary until 9 P.M., then gradually declining.

January 1, 1891. 5 P.M.: Highest temperature 100° F.

January 2d: Morning temperature 100.2° F. at 8 and at 12 M. At 5 P.M. injected 2 drops. At 8 P.M., temperature, 101.2° F.

January 3d: Highest temperature, 99.6° F. at 8 P.M.

January 4th. 4 P.M.: Temperature, 100° F. Injected 2 drops at 5 P.M. Temperature at 8 P.M., 101.6° F.

January 5th: Temperature normal until evening, when it rose to 100.2° F. at 8 P.M. Patient's weight has now increased to 132½ pounds.

January 6th: Temperature commenced to rise at 2 P.M.; by 8 P.M. had reached 101.4° F.

January 7th. 4 P.M.: Temperature, 100.2° F. Injected 2 drops at 5 P.M. At 8 P.M., temperature 101.4° F.

January 8th. 8 P.M.: Temperature rose to 101° F.

January 9th. 10 A.M.: Injected 2 drops. Temperature rose gradually to 101.2° F. at 6 P.M., and remained high until next day, January 10th, falling at 12 M. to 100° F., and rising again to 102° F. at 8 P.M.

January 11th: Temperature still high, reaching 101.4° F. at 2 P.M., then slowly declining.

The injections were continued every second day, but the temperature not accurately kept again until January 20th. The patient's weight on January 14th had fallen back to 129 pounds, on January 20th to 125 pounds. The injections were continued with slightly smaller doses, 1½ drop every second day, the temperature ranging persistently higher (from 99° to 101.4° F.) until February 2d, when the patient left the hospital. His weight on January 30th was 121 pounds.

This case is reported especially to demonstrate the reactionary effects of the injections, which proved very characteristic. There was a remarkable general improvement and increase in the body weight, which, however, declined. This patient left the hospital, voluntarily, remaining away for two weeks, and when readmitted was found to have lost ground—to so great a degree that he never rallied, but died February 21st. His body weight increased from 126 pounds to 132½ pounds while under treatment, being at this time in good physical condition. For no apparent cause he began to gradually lose weight and left the hospital, remaining away about two weeks, with the result above noted.

CASE VII. *Phthisis Pulmonalis.*—J. P——, aged thirty-two; United States; single; newsdealer. Admitted October 23, 1890. Family history, negative. Six years ago had a pleurisy. Since then has never been free from cough. Sputum at beginning of trouble frothy, now muco-purulent. Hæmoptysis two years ago; none since. Has lost flesh and strength; has night-sweats; appetite poor; bowels regular; sleeps well. Treatment with injection began January 21, 1891.

Physical Examination.—Right side, anteriorly: Dulness on percussion over apical portion; dulness less marked lower down; decidedly dull percussion sound in the subaxillary. Posteriorly: Modified percussion sound in the subscapular region; clear at the base; marked flattening on right side of infra clavicular region.

Auscultation: Right side, anteriorly, moist râles in infra-clavicular region; feeble bronchial respiration; true respiratory murmur absent at base, with modified bronchial respiration; some moist râles and pleuritic friction-sounds all the way down. Posteriorly, harsh breathing; few moist râles; fremitus increased at base. Left side, anteriorly, percussion-note modified at apex; more marked dulness extending down to base. Loud moist râles with hoarse bronchial breathing all the way down from apex to base. Posteriorly, some coarse râles and a few fine râles heard in subscapular region, and friction-sound over lower lobe.

February 11th: Has gained three pounds in weight; cough better; no night-sweats; sputum less in quantity and quality; sleep and appetite improved; tubercle bacilli found in sputum.

Tabular Record of Case VII.

	5 P.M.	98.2	80	32	Body weight, 128 pounds; an increase of 3 pounds to date.

CASE VIII.—A. S——, female, native of England, aged twenty-five; married; domestic. Admitted to hospital September 24th, 1890. Family history negative. Personal history: Has had measles, chicken-pox, scarlatina, and pneumonia. Since an attack of La Grippe about a year ago has had a cough, growing progressively more severe; has had three hemorrhages; sweats at night, and has lost flesh and strength. Expectoration muco-purulent, containing tubercle bacilli. Sleeps poorly and has no appetite. Physical examination showed signs of consolidation at the left apex.

Treatment begun on December 31st, 1890. Injected 2 drops gold and manganese solution at 5.30 P.M. At 7.30 P.M., temperature, 101.8° F.; pulse, 99; respiration, 30.

January 1st, 1891: Highest temperature, 99° F. at 1.30 P.M.; urine, 12 ounces; sputum, 2½ ounces.

January 2d. 5 P.M.: Injected 2 drops. Temperature, 100.4° F.; pulse, 88; respiration, 40. 7 P.M.: Temperature, 102° F. (highest); urine, 22 ounces; sputum, 14 ounces.

January 3d. 7 P.M.: Temperature, 101° F. (highest).

January 4th: Urine, 16 ounces; sputum, 3½ ounces. Highest temperature, 101.8° F. at 11 P.M.

January 5th. 3 P.M.: Temperature, 99.2° F.; pulse, 88; respiration, 32. Injected 2 drops at 7 P.M. Temperature, 101.1° F.

January 6th. 9 A.M.: Temperature, 97.8° F.; at 7 P.M., 102.2° F.; urine, 38 ounces; sputum, 8½ ounces.

January 7th. 9 A.M.: Temperature, 97.4° F.; 5 P.M., 99.4° F.; injected 2 drops. 11 P.M.: Temperature, 101.2° F.; urine, 57 ounces; sputum, 4½ ounces. Body weight, 107 pounds.

January 8th. 9 A.M.: Temperature, 97 2 F.; 9 P.M., 100.4° F.

January 9th. 9 A.M.: Temperature, 97.2° F. Injected 2 drops at 10 A.M. 7 P.M.: Temperature, 100.6° F.; urine, 40 ounces; sputum, 2 ounces. Marked decrease of sputum, with lessening of cough. For the next week the temperature ran from 97° to 99° F. A.M., and from 99° to 102° F. P.M.

Injections of 2 drops were made on January 11th and January 13th. After this date a new solution, twice as strong as the first, was used—*e.g.*, 1 drop of No. 2 equals 2 drops of No. 1.

January 12th: Amount of urine, 70 ounces; sputum, 1 ounce.

January 13th: Urine 31 ounces. From this time until January 20th the treatment was carried on in a similar manner, 1 drop of the stronger solution being used. The temperature ran about the same.

On January 20th, injected 1 drop; January 21st, 1½ drop; January 22d, 1½ drop; January 23d, 1½ drop. The temperature rose on the evening of January 22d to 102.4° F., and remained high all the next day, 100.4° F. at 9 A.M., and reaching 104° F. at 9 P.M. January 23d. Sputum, 4 ounces; urine, 45 ounces.

On January 24th no injection was made; but the temperature remained high all day, reaching 103.2° F. at 7 P.M.

On the morning of January 25th temperature had fallen to 99° F.; so an injection of 1½ drop was given. Temperature rose P.M. until at 9 P.M. it was 104.4° F.; pulse, 110; respiration, 40.

On January 26th and 27th temperature had fallen to normal in the morning, but ran high in the evening; 103° F., January 26th, and 102.4° January 27th.

January 28th: Injected 1½ drop; but none given again until February 1st, as the temperature ran high, reaching 102° F. in the evening.

February 1st. 11 A.M.: Injected 1½ drop. Temperature reached 101.4° F. at 3 P.M., and then declined.

February 3d. 2 P.M.: Injected 2 drops (strong solution), with little or no reaction. Temperature, 100° F. at 6 P.M.

February 5th and 7th: Injections of 2 drops, with no appreciable reaction; evening temperature varying between 100.4° F. and 101.4° F.

February 8th. 5 P.M.: Injected 2 drops. 9 P.M.: temperature, 102.6° F.; urine, 80 ounces; sputum, 1 ounce.

February 9th. 3 P.M.: Temperature, 101° F. (highest).

February 10th: Injected 2 drops. At 6 P.M., temperature, 101.4° F.

February 11th: Highest temperature, 101.2° F. at 6 P.M. Body weight, 106 pounds. Sputum reduced in quantity from 14 ounces to 2 ounces to-day, and cough not so severe. Appetite better, rests better, and sweats have disappeared. Is able to get about now, which formerly could not do. Body weight, February 20th, 110 pounds, being a gain of 4 pounds from February 3d, before which time she lost in weight one pound (between January 7th and February 3d).

The following cases of phthisis treated with the Koch lymph are added for the purpose of comparing the results with those of the cases already cited under the treatment of gold and manganese injections. The reactionary effects of the two remedies will be found strikingly similar in other particulars besides the temperature curve.

Case I. — T. M——, aged twenty-six; Ireland; widower; framer. Admitted to hospital January 26, 1891. Father died of phthisis, also a cousin. Has been very subject to colds and exposed to inhalation of fine dust from the nature of his occupation. About five years ago had pains in chest and head, and spat up blood, which latter symptom recurred two years later during a paroxysm of coughing. Since that date he began to lose flesh and strength, and about a year ago was obliged to give up work on account of constant cough, dyspnœa, and debility. Expectoration purulent and contains bacilli of tuberculosis.

Physical examination reveals diminished expansion over left chest and at right apex. Dulness on percussion over both apices. Right side, anteriorly: Bronchial breathing and bronchophony down to fourth rib. Posteriorly, left side: Prolonged high-pitched expiration and a few crepitant râles over apical region. Patient complained during treatment of some chilly sensations, but thought the cough and expectoration lessened under treatment.

January 27th, 5 P.M., received first inoculation, 0.001 milligr. Temperature, 98.2° F.; pulse, 78; respiration, 26. The temperature declined to 97.2° F. at 1 A.M., after which it gradually increased till at nine o'clock, January 28th, it reached 102.2° F., and gradually subsided. The reactionary effects grew less and less after each inoculation; the temperature, however, following the inoculations was always higher than it was on the days the inoculations were not made. Body weight January 29th, 125 pounds; January 30th, 124 pounds; February 7th, 125 pounds. Urine and sputa at first increased, afterward decreased in quantity.

Case II.—P. C— , aged twenty; single; Ireland; moulder. Admitted to hospital December 13, 1890. Family history negative. Exposed to much dust in the prosecution of his occupation, and has been very intemperate. Began to cough about two years ago, and gradually lost flesh. In August, 1890, had a hemorrhage while coughing violently, and since then has steadily lost flesh, and suffers from increased dyspnœa. About six weeks ago had another attack of hæmoptysis. Expectoration profuse and purulent, in which are found tubercle bacilli.

Physical Examination. — Dulness on percussion infraclavicular region right side, also marked posteriorly subcapsular region. Modified percussion left apical region. Bronchial breathing, subcrepitant râles, and pleuritic friction-sounds over right upper lobe, and loud, moist râles at left apex.

January 27th, 5 P.M., first inoculation, 0.001 milligr Temperature. 98.2° F.; pulse, 90; respiration, 28.

January 28th, 11 P.M., temperature reached its maximum, 101° F.; pulse, 88; respiration 26.

January 29th, 5 P.M., temperature was 100.4° F.; pulse, 92; respiration, 20; and at 11 P.M., temperature, 100 F.; pulse 104; respiration, 24. Highest points reached by temperature curve were February 3d, 1 P.M., 103.2° F.; and February 4th, 102.4° F., at 7 A.M., both occurring within twenty hours after inoculation. Body weight, December 29, 1890, 134½ pounds. January 31, 1891, body weight decreased to 121½ pounds.

Case III. R. D——, aged thirty-three; Ireland; single; laborer. Admitted to hospital January 26th, 1891. Family history negative. Body weight, 124 pounds. Last autumn had a chill, followed by cough and expectoration with loss of strength and flesh. Has night-sweats and expectorates muco purulent sputa, which on microscopic examination revealed tubercle bacilli.

Physical Examination.—Diminished expansion on right side, infra-clavicular flattening on left side. Dulness on percussion over both apices, extending down to the third intercostal space on left side anteriorly and the fourth intercostal space anteriorly on the right side.

Auscultation: Bronchial respiration and bronchophony over both apical regions with subcrepitant and loud mucous râles over left infra-clavicular region and some coarse râles over right apex.

January 27th: Gave first inoculation of parataloid, 0.001 milligr.

January 28th: Complained of malaise with increased cough and expectoration. Urine diminished. Temperature gradually increased, reaching its maximum at 11 A.M.,

103.7° F.; after which it declined, with chilly sensations.

January 29th. 11 A.M.: Temperature, 100.3° F.; and gradually became elevated until at 5 P.M. it reached 102.7°, and 103.4° F. at 12 midnight.

January 30th. 8 A.M.: The temperature reached 102.2° F.; declining to 101.8° F. at 5 P.M., when the second inoculation was given of 1 milligr.

February 1st. 8 A.M.: Temperature, 101.8° F.; 3 P.M., 101.3° F.

February 2d. 8 A.M.: Temperature, 102.7° F., after an inoculation of 1 milligr. the day before. Inoculations of 1 milligr. were administered and at stated intervals followed by more or less febrile reactions, but of less intensity than at first.

February 27th. Body weight fell to 113½ pounds, and the patient manifested every indication of failing vitality.

March 3d. Two and a half milligrammes of parataloid were administered, the temperature at 5 P.M. reaching 101° F.

March 4th, 9 A.M. The patient became delirious at 4 P.M. Temperature reached 103° F.; which gradually declined. Treatment with parataloid was discontinued, but meningeal complication did not abate up to the time of the patient's death March 6th.

This patient's temperature was elevated on the days no inoculations were made, but increased somewhat on the days that they were administered, though not uniformly. In some instances the temperature curve reached a subnormal degree before it became elevated, an effect which I have also observed from the use of the gold and manganese fluid.

The percentage of cases benefited under the treatment with parataloid has not been proportionate to those under the gold and manganese treatment, though no partiality was shown in accepting the cases for either method.

Concluding Remarks.—The cases treated at the hospital were not selected, but subjected to treatment as they presented and expressed a desire to receive the injections. All were very much reduced physically, and manifested extensive pulmonary lesions. The nutrition uniformly improved—in some of the cases the expectoration was remarkably decreased—especially reduced in Case VI., A. S——, where the amount was lessened from fourteen ounces to one ounce in twenty four hours, though at first it was slightly increased. The rapid gain in body weight in several instances was remarkable, following improvement in the appetite and the functions of digestion and assimilation.

The improvement in the respiration does not appear so readily as the other indications of benefit, though cough and expectoration are soon lessened, fewer râles and less pronounced dulness over affected areas are evidences of amelioration which are not long to supervene.

In some of the cases a very pronounced reaction followed the injections, but it is desirable to avoid such effects as far as possible by moderate doses, for I believe the best therapeutic effects are assured when little or no very decided reaction is manifested.

The two private cases reported, both incipient cases of pulmonary tuberculosis, were not confined to the house during treatment, but attended to their daily avocations without any inconvenience. The general amelioration was prompt. Cough, expectoration, and throat irritation were entirely relieved after six injections in one and eight in the other case. Both immediately began to experience better appetites, and rapidly gained in body weight. This is the class of cases in which the most decided beneficial effects from the treatment may be expected.

Before these patients were subjected to this method of treatment, inhalations, sprays, etc., were tried for some time without effecting such relief of the throat irritation and cough, which, in so short a time, yielded to the hypodermic injections. I have many private patients under treatment progressing equally as well as those above cited.

In conclusion, I may now say that in my practice of over five hundred injections, there has neither resulted an abscess, nor even a trace of inflammation of the skin about the seat of the punctures, which I attribute largely to my antiseptic hypodermic syringe, described in the MEDICAL RECORD, January 31, 1891.

1013 MADISON AVENUE.

NOTES IN MEDICAL JURISPRUDENCE.

BY HENRY A. RILEY, ESQ.,

NEW YORK.

The Fayerweather Will Case.—The Fayerweather will has attracted more attention than almost any testamentary document of recent years, and this was largely due to the fact that the princely sum of over $2,000,000 was given to colleges and hospitals. The three executors were made residuary legatees, and when it was found that the estate to be divided between them would amount to about $3,000,000 the public supposed that there was some private agreement by which this immense sum would go to other objects than the making the executors millionnaires. This turned out not to be the case and the heirs began a contest.

This has, however, been interrupted by the sensational statement that the executors had made a deed of gift covering the vast residuary estate, retaining nothing for themselves except their legal fees.

The deed of gift is a long document and makes a large number of gifts to various educational institutions and hospitals.

Yale College is the largest beneficiary, and the $300,000 given by the will is increased so that it will probably amount to over $500,000.

The following hospitals were remembered in the original will as follows:

Presbyterian Hospital, New York	$25,000
St. Luke's Hospital, New York	25,000
Manhattan Eye and Ear Infirmary, New York	25,000
Woman's Hospital, New York	10,000
Mt. Sinai Hospital, New York	10,000

The deed of gift makes a number of new hospitals beneficiaries, besides giving additional amounts as follows:

Mt. Sinai Hospital	$15,000
Presbyterian Hospital	25,000
Woman's Hospital	200,000
Manhattan Eye and Ear Infirmary	25,000
New York Eye and Ear Infirmary	25,000
Manhattan Dispensary	25,000
Montefiore Home for Chronic Invalids	25,000
St. Luke's Hospital	25,000
New York Cancer Hospital	25,000
Society of St. Vincent de Paul	50,000

The only direction for the use of these sums is as follows: "Each of the gifts mentioned in the article is to be used for the endowment of beds or some other use which in the best judgment of the officers of the institution is best fitted both to be of the greatest service and at the same time best to perpetuate Mr. Fayerweather's memory."

It is not yet known what effect this deed of gift will have upon the contest, but it ought to put an end to it at once.

The Morris Plains Lunatic Asylum in Politics.—It is stated that the Morris Plains Lunatic Asylum is suffering from a severe attack of politics.

The New Jersey Legislature has just passed a law removing, without apparent cause, the present Board of Managers, but has not placed their successors in office, and as a result a number of patients who have been declared sane are unable to get a discharge. Superintendent Harris, of the medical department, has sent certificates of dismissal to Dr. James S. Green, of Elizabeth, the late vice president of the asylum, but he has declined to sign them because he says the legislature has terminated his connection with the asylum. The law requires his sig-

nature to the certificate before a patient can be discharged, and as he does not think he has power to act a number of persons are unlawfully detained.

The Tariff and the Lymph. — Assistant Secretary Spaulding has made a ruling that a parcel containing Professor Koch's lymph is properly subject to duty at the rate of twenty-five per cent. ad valorem under the provision for "medicinal preparations, including medicinal proprietary preparations."

Two bottles containing the lymph have recently been seized in this city because of non-payment of duty. They were sent by mail to physicians in this city.

It has been supposed that the lymph would be admitted free, but the Treasury authorities do not think the law will permit such admission. The price of the lymph is not high and the duty will not be burdensome in any case, though the delay in obtaining possession of the medicine may often be annoying.

The Responsibility for Defective Pavements.—The danger from defective sidewalks and the masses of ice or snow which careless lot owners may permit to accumulate makes the frequent decisions of the courts of much interest.

A recent case in New York in the Court of Appeals places the responsibility for accidents squarely on the city authorities, and removes it from the lot owners even when they are apparently negligent and an ordinance expressly makes it their duty to keep the sidewalks clear.

The charter of the City of Rochester imposes on each lot owner the duty of keeping his sidewalk in good repair, and the Superintendent of Streets can, after written notice to repair, make the repairs himself and collect the cost from the lot owner.

A person who was injured by stepping into a hole brought suit against the city, and recovered a judgment, which was paid. The lot owner was notified to defend the suit and was represented on the trial. Under these circumstances the city brought suit against the lot owner to be reimbursed for the amount of the judgment. The Court of Appeals says, however, that there is no liability on the part of the lot owner to reimburse the city. The grounds for this decision are of general interest and are stated as follows: "We have thus referred at length to many of the cases holding the non liability of the lot owners, for the reason that there seems to have been quite a common impression, in which judges and lawyers have shared, that abutting owners are in some way liable for damages occasioned from their neglect to keep sidewalks in repair when that duty is in any way enjoined upon them. It seems to us that there never could have been any logical cause for such impression, and it seems it has no foundation in the reported cases. Any other conclusion than that reached by us would, we think, be most unfortunate, as it would tend to relax the vigilance of municipal corporations in the performance of their duties in respect to the repair of streets and highways, and impose that duty upon those who might be utterly unable to discharge it. It would tend directly to demoralize the public service and lead to disorder, decay, and impassibility of the public highways."

Dressed Beef and Health Ordinances.—Virginia, not long since, passed an alleged health law, forbidding the sale of any meat slaughtered at places more than one hundred miles distant, unless such meat had been inspected and a fee of one cent a pound paid. The United States Supreme Court has just decided that the law is an illegal attempt to restrain trade, and is void. The claim that it was necessary as a health regulation was not regarded as worth considering. A similar law ran the gauntlet of the courts in Minnesota a short time since with a similar result.

Clothing and Disease.—A large amount of clothing is made in this city, mainly for the out of town trade, in tenement-house rooms which have acquired the title of "Sweaters' dens," from their filthy and crowded condition. It is claimed that much of this clothing comes from quarters where disease is rampant, and it is feared that the germs of such infectious diseases as diphtheria, smallpox, measles, scarlet-fever, etc., may be distributed through the country by means of clothing made where these diseases are prevalent. The Clothing Operatives' Union of Boston has sent an agent to this city to investigate the matter and see if the complaints about the dangerous character of the clothing are well founded. If substantiated an effort will be made to secure legislation on the subject.

Car Stoves and Accidents.—The recent terrible disaster in the tunnel leading from the Grand Central Depot, by which six persons were either crushed to death by the collision or else were burned by the resulting fire, will call renewed attention to the various devices for heating cars. The New York Legislature has passed a law requiring the removal of the stoves from passenger cars and the substitution of some other form of heating, but this law has been largely disregarded by the New York and New Haven Railroad, and a good many of its cars still have the death-dealing stoves.

It is quite likely that the inquest now in progress will throw the responsibility in part on the officials of the railroad, and if so it will be the duty of the District Attorney to bring the matter before the Grand Jury.

People must Use their Eyes.—Some curious cases get into the courts from the failure of persons to make good use of their eyes, but who hope, nevertheless, to make other persons pay them for the harm resulting. In a recent New York case a merchant had a heavy truck in one part of his store, and a customer following a clerk about, looking at goods, was injured. He brought suit against the merchant, but the Court decided against him, saying that the question to be decided was whether the mischief could have been reasonably foreseen. When such appliances are not placed so as to threaten danger to those visiting the store on business, and are in full sight, the merchant is not liable for accidents which result from carelessness and inattention to the surroundings.

There was a similar case not long since where a person brought suit because he stumbled against a figure on a stairway upon which clothing was displayed. In this case also the Court held there could be no recovery.

Accident Insurance and Paralysis.—A life insurance policy issued by the Pacific Mutual Life Insurance Co. provided that the amount of the policy should be paid in the case of accidental and violent injury where the claimant should "suffer the loss of the entire sight of both eyes or the loss of two entire hands, or two entire feet, or one entire hand and one entire foot." The insured was accidentally shot in the back, producing paralysis, so that he lost the use of the lower part of his body and of both feet. The company contested the case before a Wisconsin court, but was defeated.

The Court said that the loss of both feet was as complete as if they had been cut off and that the policy was broad enough to cover injuries of the kind mentioned.

Appendicitis in the Female.—As the result of personal observations Dr. Richelot presents the following conclusions: 1. On account of the proximity of the uterine annexes the diagnosis of appendicitis is more difficult in woman than in man. Suspicion is naturally aroused when the pain and induration are well up in the iliac fossa and entirely to the right, and should always be excited whenever the symptoms are markedly predominant on the right, even if there be evidence of lesions to the left; even if the pain be referred to the uterine annexes, and even if rectal and vaginal touch reveal induration at the right border of the uterus. 2. With the reserves already formulated surgical intervention should be bold and early. The prognosis of the disease left to itself is extremely grave. The earlier the operation the more it approaches in relative benignity the modern operations in the region of the uterus.—*L'Union Médicale.*

New York, March 21, 1891.

THE TREATMENT OF PNEUMONIA.

We offer no excuse for again bringing to the attention of our readers the subject of the treatment of acute lobar pneumonia. This disease is still a reproach to our art, even more than so phthisis pulmonalis, and there is no subject which deserves more earnest study.

Dr. W. S. Fenwick, of London, has recently presented (*The Lancet*, January 31 and February 7, 1891) the results of the analysis of one thousand cases of pneumonia treated at the London Hospital, between the years 1880 and 1890. These thousand cases include only such as were in the hospital for more than twenty-four hours before a crisis or death occurred. The elimination of such cases was very proper, for forty-nine per cent. of them died, and a therapeutical study of them could have only a very negative and melancholy interest value. Dr. Fenwick begins by referring to that first principle in pneumonia therapeutics, the individualization of the cases. Venesection and tartar emetic, which would be death to most city cases, may be, he says, the most potent of all remedies in the rural districts. He divides his cases into the sthenic and asthenic. Under the sthenic cases he includes all in which the temperature averaged above 103° F., while in the asthenic cases the temperature ranged below this figure. He excludes all cases of secondary pneumonia. The sthenic cases, five hundred and two in number, appear to have been submitted to three kinds of treatment, viz.: 1. Cases in which the treatment consisted in the application of hot poultices to the chest, combined with the internal administration of various expectorant and tonic remedies. 2. Cases whose medicinal treatment consisted entirely of quinine in large doses. 3. Cases in which the disease was combated upon general antipyretic principles, similar to those employed in the treatment of other acute specific fevers.

With regard to the first form of treatment, some interesting facts are given bearing on the relations of the temperature and the mortality in these cases. In 324 cases the average temperature ranged between 103° and 104° F., and of these 60, or about 18.5 per cent., died. In 169 cases the average temperature ranged between 104° and 105° F., and of these 51, or thirty per cent., died. In 16 cases the average temperature exceeded 105° F., and of these 9, or 56.2 per cent., died.

A study of the time of death showed first, that during an ordinary attack of acute pneumonia death is most apt to supervene about the fifth day, *i.e.*, at the height of the fever; secondly, that after the eighth day the danger to life increases enormously with each day that the crisis is deferred; and thirdly, that the crisis itself is a period of very considerable danger.

With regard to the quinine treatment, it was found that this drug was given alone and in remedial doses in 52 cases. In the cases with a temperature varying from 103° to 104° F., nineteen per cent. died; of those with a higher temperature, twenty-five per cent. died. The results, therefore, were unfavorable to the use of quinine.

In both this and the first class of cases, the mortality exceeded twenty per cent.

The clinical histories showed that fatal failure of the heart was of frequent occurrence, and seemed to result from the sudden withdrawal of the stimulating action of the fever.

The antipyretic treatment by drugs alone was not employed in a sufficient number of cases to enable our author to draw any conclusions. In 26 cases the antipyretic treatment consisted in the use of ice-bags or Leiter's coils applied over the lung. Four patients died, or about fifteen per cent., and hence the conclusion is drawn that this treatment answered better than either of the two others.

The cold pack was used in 26 cases, with 4 deaths. Systematic sponging was used in 65 cases, with a mortality of only 12.8 per cent. The ice-cradle was used in 43 cases, with a mortality of only seven per cent. Naturally, in all the above cases stimulants, such as ammonia and alcohol, were given, as well as at times quinine.

Taken altogether, there were 108 cases treated by applications of cold in one form or another, with a mortality of ten per cent., as against twenty-three per cent. by other methods.

There were 285 cases of asthenic pneumonia so-called, or types in which the average temperature ran below 103° F. This form of pneumonia is the one which usually supervenes in the course of chronic disease, and its fatality is very great.

Among 240 cases treated by poultices, tonics, and stimulants, the mortality was from thirty to fifty per cent. Some evidence is presented to show that quinine is of value in this class of cases. Antipyretic treatment is, however, not only valueless but dangerous, as is also venesection.

The study of Dr. Fenwick's cases reveals the fact that the mortality of acute lobar pneumonia increases with the severity, and also with the mildness, of the fever. In other words, more deaths occur the more the temperature-curve tends to rise above or sink below an average of about 103° F.

Dr. Fenwick presents the results of two distinct methods of treatment. In the first the chief remedies were aimed at relieving the condition of the lung; and while stimulants were freely administered with the object of whipping up the flagging heart, the cause of its physical lameness was allowed to proceed unmolested. The result was that, among 552 cases so treated, the mortality exceeded twenty-three per cent., although alcohol was exhibited in no less than seventy per cent. In the second case a method of treatment was adopted with one special

object, to economize cardiac force by minimizing the injurious influences of fever. In 108 cases of similar severity to the foregoing, the treatment consisted in the systematic reduction of temperature by means of sponging or ice-cradling. Of this number only 45 (forty-one per cent.) received alcohol, and only ten per cent. died.

A very important point was brought out in connection with treatment at the time of crisis. It was shown that when special attention was paid to the danger attending this period not a patient died.

Dr. Fenwick's experience points to the importance of looking upon pneumonia not as a local disease of the lung, but as a specific fever, the lung disease being to it what the typhoid ulcer is to the fever in that disease.

VOLUNTARY PATIENTS IN HOSPITALS FOR THE INSANE.

SHOULD voluntary patients be received in hospitals for the insane? Dr. Ralph L. Parsons thinks they should, and in an able article printed in the February number of the *Journal of Nervous and Mental Disease* he sets forth his reasons. The patients are those who are near, but not yet across, the border line of insanity, those who are in the incipient stages, and those who are the victims of a habit. It is an undeniable fact that such patients can best be treated in an asylum, and yet to enter an asylum, as the laws of New York and many other States now stand, leaves an opprobrium that few dare to brave. To have voluntary patients with the certified insane elevates the hospital in the eyes of the public (it is something more than a "lunatic asylum" or "mad-house"); the discipline is improved; officials are more apt to be gentle and attentive to patients, and the patients themselves are improved by mingling with persons who are not insane. The objections raised against the admission of private patients are: first, lack of room; secondly, because a suspicion might exist on the part of the public to the effect that the alleged voluntary patients were, after all, detained against their will; thirdly, because the law is supposed to require the restriction. The objection of lack of room applies only to State hospitals. If these cannot accommodate more than the certified insane it is only just that voluntary patients be excluded. Private hospitals do and should be permitted lawfully to receive the voluntary patients. The second objection is a myth. No such suspicion has been expressed in the past, nor is it likely to be in the future. The legal penalties for the detention of uncommitted patients are such as to avert not only the fact, but the suspicion even of their detention. Massachusetts has a law permitting voluntary patients receiving care and treatment in hospitals for the insane, and according to Dr. Edward Cowles, Medical Superintendent of the McLean Asylum, since its enactment in 1880 it has yielded most beneficial results. "It has not only been a blessing to many patients who have gladly availed themselves of its benefits, but it has done good to the asylum itself in stimulating improvement in the care of all its patients." New York's law should be modelled after this one. Then patients who are in the early stages of insanity, when it is most amenable to treatment, would seek advice and treatment, and much suffering would be avoided.

OUR SUPERFLUITY OF HOSPITALS.

THERE has recently been a pretty decided expression of opinion to the effect that the business of building and endowing hospitals is rather overdone, and that more good can be done to one's fellow-man by endowing educational institutions. So far as this view applies to medicine it means that we need better doctors more than we need larger hospitals. It is always, and naturally has been, the case that vastly greater sums of money have gone to institutions for the care of the sick than to institutions for the education of those who will treat the sick. Yet it is evidently quite as important for the sick to have intelligent medical and surgical care as to have a good bed and board. We showed, in discussing this topic a year ago, that in the past fifteen years the number of hospitals in this city had doubled, while the population had increased about one-third. In two city institutions alone twenty-five thousand patients are treated annually. More than this, the amount of free work done in hospitals has increased ninety per cent. in the past decade alone. It looks, therefore, as though in time the hospital would be as much an enemy to the general practitioner as the dispensary.

We trust that our hospitals will be well supported, for they are needed, and the work they do is of incalculable value; but the thoughts of dying millionaires might be profitably attuned for a time to our colleges. It is impossible to educate medical students as they should be educated unless the college is endowed.

MURDER AND INSANITY.

A REMARKABLE case, with a remarkable termination, has just been upon trial at Buffalo, N. Y. A young woman, seventeen years of age, named Sarah McMullen, enticed two small children upon a trestle bridge and pushed them over, causing the death of one. The murderess afterward went to a lower bridge, eight feet above a creek, and jumped off into the water. She was easily rescued. The evidence showed that the murder was deliberately planned and was actuated apparently by jealousy; also that suicide was intended, but that the woman's courage gave out. The plea of the defence was insanity. It was shown that she had always been moody, was given to fits of dejection, and behaved at times unaccountably. The aunt to whom a farewell letter was written, gave several instances of insanity in the family. The witness's sister had been confined four times, covering a period of fifteen years, in the insane asylums at Buffalo and at Utica. A brother was in the county asylum, having previously been in the State asylum. He had been insane eighteen years. The witness's father, although never confined, had a delusion for many years, and lasting until his death, that his life was in danger. In his last sickness he was in constant fear of poison. The McMullen girl's mother was nervous, quick tempered, and hysterical, and her father—the witness's brother—was a hard drinker. The witness's father and mother were first cousins.

The jury rendered a verdict of not guilty on the ground of insanity, closing a case which, according to the daily press, has no modern parallel. While this is hardly true, it is remarkable that such a verdict should be given when the evidence showed that the girl must have known the

nature of her act; for she deliberately planned it, and carefully carried out all the details except that of her own suicide. Such a verdict shows that the courts are weakening a little in their adherence to the legal conception of insanity, and are coming over to the medical view of it. Courts have, heretofore, tried to determine whether the defendant knew the nature of the murderous act and was conscious of the difference between right and wrong. This has been the supreme test.

Medical men have held, on the other hand, that the main fact to decide is whether the patient has mental disease, and whether the criminal act was the result of such disease.

MEDICAL CO-EDUCATION.

One of our popular monthlies has taken the trouble to secure a discussion of the subject of the admission of women to the future Johns Hopkins Medical College. This seems like threshing old straw. The ladies have got the money and the Trustees have taken it and consented to co-education; and the boys and girls will be able to labor together. But the medical world has learned that the Johns Hopkins College which is to be cannot be a great one with the sum of money supplied to it, and hence the question of co-education there lacks some interest. The hospital is a very expensive one, but it is small, and does not furnish the clinical material necessary for a great school. The increasing endowments of the Colleges in New York, Philadelphia, and Boston are rapidly making these the real centres for the most advanced medical teaching, as well as the best original work. There are now better chances for women in this city than the proposed Baltimore institution can possibly pre sent.

The interest in medical co-education is, therefore, only a general one. The experiences of the past have not favored it; but perhaps at Johns Hopkins they can do better, especially if they give only the graduate studies and a laboratory course. The plan of taking young men and women at the age of eighteen and training them up together in medicine is dangerous and probably unwise.

QUARANTINE AT NEW YORK.

Mr. Henry D. Plimsoll, in a letter to the *Times*, calls attention to the antiquated system of admitting ships to the port of New York, and justly charges us with maintaining quarantine, "the offspring of ignorance," during this enlightened decade. Vessels arriving here after sundown must remain at anchor in the Narrows until the following day at sunrise, and, as the sun sets in midwinter at about 4.30 o'clock and rises about 7.30 o'clock, it follows that a detention of about fifteen hours may ensue, and this, says Mr. Plimsoll, in the present age, is just as absurd as the ancient system of forty days detention, as implied by the word quarantine, derived from *quarenta*, forty.

Medical science, he adds, in the two continents advances side by side, and the cable places them in immediate communication, so that any disturbance in the sanitary condition of any part of one of the continents is at once communicated to the other, and therefore can be specially guarded against.

Quarantine, in its original sense, has been abolished from all the countries of Europe except Spain and Portugal. For it there is substituted the system of inspection, and detention only of vessels with a foul bill of health, or containing persons suffering from infectious fevers. The New York quarantine is, of course, not a severe one, but it is annoying and unnecessary. We trust that Mr. Plimsoll's letter will set our authorities to thinking; it is not the first time this just complaint has been made.

News of the Week.

The Fourth Congress of the German Gynæcological Society will be held at Bonn from May 21st to the 23d.

A Medical College in Mid-China.—At Hang-Chow, in Mid-China, there is a large mission hospital under the charge of Dr. David Main. It was built expressly for the purpose in 1885. As the Chinese have no name for the hospital, the institution is commonly known as "The Universal Benevolent Healing Office." A medical class is in constant training at the hospital, and last year eight of the students "satisfied the examiners" at the end of a curriculum which, in one respect at least, would receive the approval of our own General Medical Council, inasmuch as it was of five years' duration.

We are Interested in learning from an English exchange that a Miss Clarissa Caldwell Lothrop, who was confined for two years in an asylum in Utica, United States, is forming an "Anti-Kidnapping and Lunacy Reform Union in America." The president is Mr. Bronson Murray, of New York, the secretary being Miss Lothrop herself; and the treasurer, Madame Demarest. From the complaints that reach us it seems likely that there will soon have to be formed a society for promoting the commitment of lunatics to lunatic asylums.

A Physician's Strange Will.—Dr. Charles F. Heuser, an eccentric physician living in Baltimore, has just died, leaving a will directing that within twelve hours after his death a surgeon should cut out his heart in the presence of witnesses, after which his body should be cremated and the ashes placed in little silver phials and distributed among his friends. The first part of the direction was carried out by an operation performed by Dr. Adolph Boehm, in the presence of a number of physicians and medical students, besides some friends of the dead doctor. The heart of the deceased was removed and then replaced in the body. The doctor's peculiar request was accounted for by his horror of being buried alive. It has been a family custom of the Heusers to have their bodies mutilated after death. Dr. Heuser, after his wife's death, drove a knife into her heart.

Parataloid is being used at several points in Chicago, but it is yet too early to state, with any degree of positivism, what the outcome will be. This much, however, has been noted at the Presbyterian Hospital, that upon cases of pulmonary tuberculosis of any considerable standing there has been no appreciable improvement. Lupus shows the most prominent favorable advancement, though a cure has not yet taken place. The effect upon tuberculous joints and glands is also, as yet, in the experimental stage.

A French Physician on occasions of state is entitled by law to wear a black gown of bolting cloth (*étamine*), the back and front of which are of crimson silk bordered with ermine; a black coat *à la Française;* cambric bands, and a cap of crimson silk with a border of gold lace.

Death of Hartnack.—The death is announced at Potsdam of the well-known optician, Professor Edmund Hartnack, with whose microscopes everyone is familiar.

Surgical Treatment of Cancer of the Liver.—Cancer of the liver, usually considered a perfectly hopeless disease, has been treated successfully by Terillon, who removed a cancerous mass from the left lobe.

Direct Application of Tuberculin to Pulmonary Cavities.—In a lecture delivered at Halle on February 18th, and published in the *Münchener medicinische Wochenschrift*, No. 8, 1891, Dr. Edmund Leser gives full details of two interesting cases in which he cut down upon, and laid open and emptied, large pulmonary cavities of tuberculous origin, with the object of treating the diseased portion of lung by the direct application of Koch's fluid. In each case the cavity was near the apex of the lung. Both the patients were adults. The results of the operation itself proved very satisfactory, and up to the date of the delivery of the lecture, the patients, it is stated, had improved very much. In the first case, a one per cent. solution of Koch's fluid was applied to the inner wall of the exposed cavity by means of a brush. In the second case, solutions of increasing strength were injected three times into the cavity. In both instances the application of the fluid was followed by well-marked febrile reaction, together with dyspnœa, pain in the affected region of the lung, and aggravation of the cough. There was also considerable increase in the amount of fluid secreted from the walls of the cavities.

The Medical Society of the Missouri Valley will meet at Omaha, Neb., March 19th and 20th. Papers will be read by Drs. A. F. Jonas, Omaha; J. M. Emmert, Atlantic; Flavel B. Tiffany, Kansas City; Donald Macrae, Council Bluffs; S. Stewart, Council Bluffs; J. E. Summers, Jr., Omaha; J. F. White, Council Bluffs; S. G. Gant, Kansas City; H. Gifford, Omaha; Rebecca Hanna, Red Oak; and J. P. Lord, Omaha.

Some Curiosities of Science.—The important fact is established that the electrical resistance of a mummy is 6,000,000 ohms. The cranial temperature of the citizens of Colorado is 1° F. higher than that of their less favored eastern brethren. The human race annually absorbs three million pounds of nicotin, one drop of which will kill a cat. A Birmingham gentleman carried a pea in his right ear for five years and seven months, when it was successfully removed by a general practitioner.

A Remedy for Phtheiriasis.—One of the best washes for the removal of the ubiquitous parasite from the hairy parts of the body, is a decoction of quassia to which a little borax and glycerine have been added.

The Influenza has reappeared and become very prevalent in Chicago. The Island of Sumatra is suffering in the same way. It will puzzle the demographer to find why these two places are selected for epidemic recrudescence.

An Insane Asylum Burned.—On March 14th the Central Insane Asylum of Tennessee was burned and six of the inmates lost their lives.

A Hydrophobia Scare.—Two persons were bitten by dogs alleged to be mad, in Orange County, N. Y. The bitten persons have come to New York to be treated.

Garfield Tea, so-called, is said to be composed chiefly of senna, fennel, marshmallow, and couch grass.

The Official Regulations as to the Sale of Tuberculin have appeared. The chemists are to obtain their supply from Dr. Libbertz, who will continue to prepare the lymph under the supervision of Professor Koch. It will be sold in sealed bottles containing from one to five cubic centimetres, and marked with the date of preparation. The chemists are to use the same precautions as with poison, and only to sell it in the original bottles and upon the written prescription of medical men. A special book is to be kept for the entry of sales, etc., and in each case the quantity sold, the date of preparation, of purchase, and of sale, and the name of the physician prescribing it must be noted. Six months after preparation the lymph may no longer be sold. Bottles six months old should be returned to Dr. Libbertz, who will exchange them for new ones without extra charge. The price has been fixed at six marks (6s.) for a cubic centimetre, and twenty-five marks (£1 5s.) for five cubic centimetres.

The German Congress of Internal Medicine.—The tenth annual meeting of the above Congress will take place at Wiesbaden from April 6th to 9th, under the presidency of Professor Leyden, of Berlin. The subjects for general debate are: 1. Biliary Calculous Disorders, to be opened by Dr. Naunyn (Strasburg) and Dr. Fürbringer (Berlin). 2. Koch's Remedy in Pulmonary Tuberculosis and other Internal Tuberculous Diseases. 3. Angina Pectoris, to be opened by Dr. A. Fraenkel (Berlin) and Dr. O. Vierordt (Heidelberg). The following is a list of the papers promised for the meeting: Dr. Kahler (Vienna): Intermittent Albuminuria. Dr. Mosler (Griefswald): the Treatment of Leukæmia. Dr. T. Schott (Nauheim): the Differential Diagnosis of Pericardial Exudation and Cardiac Dilatation. Dr. Knoll (Prague): (1) Disorders of Circulation; (2) Morbid Changes of Striped Muscle. Dr. Brieger (Berlin): Chemical Changes in Infectious Diseases. Dr. Rosenstein (Leyden): the Diagnosis of Hypertrophic Cirrhosis of the Liver. Dr. Quincke (Kiel): Hydrocephalus. Dr. Eichhorst (Zurich): Observations on the Patellar-tendon Reflex in Tabes Dorsalis. Dr. Edelfsen (Kiel): (1) the Origin of the Vesicular Murmur; (2) Varicella Statistics. Dr. Tappeiner (Munich): the Diuretic Action of Phenylmethyl pyrazolcarbonic Acid. Dr. Friedländer (Leipsic): (1) the Method of Mathematical Diagnosis of Acute Articular Rheumatism and of all forms of Central Rheumatism; (2) Etiology of Bright's Disease. Dr. Leubuscher (Jena): Clinical Researches on Acid Excretion in Mental and Nervous Diseases. Dr. Schmaltz (Dresden): Examination of the Specific Gravity of Human Blood, and its behavior in Anæmic Conditions. Dr. Mordhorst (Wiesbaden: Diagnosis and Treatment of Gout. The secretary of the Congress is Dr. Emil Pfeiffer of Wiesbaden.

An Inadequate Frontispiece.—In the sacred name of art, and on behalf of womankind as it blooms and fructifies in the sunny South, we wish to protest against the title-page of our picturesque contemporary, *The Dixie Doctor*. The said title-page contains the portraits of Drs. McDowell, Long, Sims, and Battey, each artistically delineated and set in the four corners, like the angels of the Apocalypse. Nobody can complain of such tribute to historic greatness. But in between these is the artist's conception of a doctor's office, with a desk, a doctor, and a lady. It is this Georgia simulacrum of the professional workshop with which we must, in the most amiable spirit, find fault. In the first place, we note that the doctor in the picture sits comfortably back in a cushioned chair, while the lady is obliged to sit *vis-à-vis*, on a hard-bottomed rectangular arrangement, to her most evident discomfort, and with the probable peril, in time, of gluteal induration and articulo-muscular overstrain. The situation of the lady is unjust to the chivalry of the South. Besides, the patient herself is not all our fancy has painted, or our vision realized, of the lovely types of womanhood which flourish among the cotton, the sugar, and the corn. We beg the artist to reconstruct his inadequate creation. Let him first see a real Southern doctor meet and treat his countrywoman, and he will blush at his performance.

The Number of Students in Paris.—With its five faculties and the High School of Pharmacy, the University of France counts in Paris more alumni than any other in the world. In 1890 there were no less than 10,174 students on the rolls, these figures including 986 foreigners, 759 of whom are studying medicine. In 1889 the number of students registered was 10,375. These figures do not include men pursuing their studies at the Collège de France, the Muséum d'Histoire Naturelle, the École de Chartes, and kindred special establishments.

Notice to the Military Surgeons of the National Guard.—Dr. Senn, of Milwaukee, Surgeon-General of Wisconsin, is desirous of obtaining the name and address of every military surgeon of the National Guard in the United States, for the purpose of taking the necessary preliminary steps toward the formation of a permanent national association.

Change of Time of Holding the Meeting of the National Association of Railway Surgeons.—On account of the meeting of the American Medical Association at Washington, D. C., on May 5th, and continuing to the 8th, it has been thought best, by the officers of the National Association of Railway Surgeons, to change the time of meeting from May 7th to April 30th. The meeting will be held at Buffalo, N. Y., beginning at 10 A.M., and continuing to May 3d. This change will give the surgeons who have a long distance to travel, an opportunity of attending both meetings on one trip.

The Seventh International Congress of Hygiene and Demography will be held in London, August 10 to 17, 1891. H.R.H. the Prince of Wales, K.G., will preside. The aim of the Congress is to awaken public interest in the progress of hygiene and demography, by which latter term is understood the study of the life conditions of communities from a statistical point of view; to afford persons interested in these subjects an opportunity of meeting, with the object of advancing their progress; and, by conferences and debates, to elucidate questions relating to hygiene, demography, and public health. The governments of all countries, municipalities, county councils, and other provincial administrations, public health authorities, universities, colleges, and all societies which are occupied in the study of the sciences more or less immediately connected with hygiene, are invited to co-operate and appoint delegates to represent them at the Congress. An exhibition of articles of hygienic interest will be held in connection with the Congress. Excursions will be arranged to various places of especial interest to hygienists.

Examinations for Appointment in Medical Department of the Army.—An announcement was recently made that an army medical board would be in session in New York City during April next, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies. At the time of that announcement there were only five vacancies to be filled. Recent Congressional legislation has, however, permitted the retirement of certain officers, so that there are now fourteen vacancies in the grade of assistant surgeon, with the probability that the number will be increased to seventeen by the time the examining board begins its labors. As already stated, persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before April 1, 1891, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the Board. Further information regarding the examinations may be obtained by addressing the Surgeon-General U. S. Army, Washington, D. C.—C. Sutherland, Surgeon-General U. S. Army. Washington, D. C., March 4, 1891.

Doctors in the United States Senate.—The statement is made that Dr. J. H. Gallinger, of New Hampshire, is the first physician who has ever been elected to the United States Senate. This is a mistake. Maryland, Florida, and we believe other States, have elected medical men to the Senate.

Treatment of Red Nose.—When red nose is due to acne rosacea, Unna gives ichthyol internally, in doses of five grains, and prescribes at the same time lotions of the same substance in aqueous solution. At night, the following paste is applied to the affected organ:

℞. Sulphur. ..... ℥ss.
Rice powder ..... ʒiv.
Ointment of zinc oxide .... ℥v.
Mix, and make a pomade

If the patient is scrofulous or debilitated, he also orders cod-liver oil, syrup of iodide of iron, etc.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 5, 1891.

THE VICE-PRESIDENT, R. C. M. PAGE, M.D., IN THE CHAIR.

Donation of Furniture.—The following resolution was adopted:

Resolved, That it is the feeling of the Academy that the gift of the elegant and substantial platform furniture for Hosack Hall by the President, Dr. Loomis, should be noted in its records, and that its sincere thanks should be extended the donor.

A New Method for the Direct Electrization of the Stomach, with Demonstration.—DR. MAX EINHORN read the paper, which will appear in a future issue of the MEDICAL RECORD.

Laceration of the Perineum.—DR. HENRY J. GARRIGUES read the paper which dealt chiefly with the anatomy of the perineum and the parts involved in lacerations by the child's head. The common way of classifying perineal lacerations, he said, took only the extent of the tear into consideration. In his opinion this division, based on the degrees or extent of the laceration, overlooked the most important point. In a paper published in the *American Journal of Obstetrics* in 1880, he had called attention to the confusion arising from speaking of the canal leading up to the uterus simply as the vaginal canal, instead of taking note of the difference between the vulval portion and the vaginal canal proper, which was as marked as the difference between the body and the cervix of the uterus. The inner, the outer, and the vulval rings were the two places where laceration commonly began during childbirth. The upper ring, being the narrower of the two, was more frequently torn than the other. After mentioning the several muscles entering into the formation of the vaginal ring, the author emphasized the importance of the levator ani, which was by far the strongest. It formed a horse-shoe shaped muscular expansion which was open in front, and was generally described as two muscles, the levator ani proper and the coccygeus. Under all circumstances they formed together a pelvic diaphragm corresponding to that which limited the cavity above.

Regarding the perineal body, he said a great deal had been written about it, and different authors had assigned very different shapes to it, but a study of the pelvis showed that in different women a great variety of shapes obtained. Sometimes the whole space between the vagina and rectum up to the uterus formed a triangular sulcus; in some cases it could be distinguished as two spaces, upper and lower, the latter, however, then deserving alone the name perineal body. Small as the body was, it was of importance as showing the centre of the perineal region where the muscles and ligaments came together. It kept the vagina and rectum in proper relative position. During childbirth it formed a strong barrier against which the child was being pushed from above. During the act of expulsion its resistance was often overcome and laceration took place.

Besides the two rings already mentioned at the outlet and entrance of the vagina, a third one, formed by the internal and external sphincter ani muscles, must be taken into consideration. Its function was to close the intestinal canal. While the head was being pushed against the vaginal ring it might break through the rectum. Other forms were, a tear through the vaginal ring, a tear through the vulval ring, a tear through both vaginal and vulval rings, a tear involving the vaginal rings and sphincter ani; a nick involving the integument at the fourchette which readily healed if the muscles beneath were intact to hold the parts in apposition. The tears involving the muscular structure might take place when they were in a state of tension, without breaking the mucous membrane or integument. The usual direction of the tear involving the muscular rings was longitudinal, but the appearance after a time, owing to retraction of the muscular fibres, was as if a transverse tear had taken place.

Where all three rings were torn through, natural cures must be exceptional, and no man would wait. Where the primary operation had not been performed, the intermediary might be tried, although he had had little experience with it. A secondary operation would be necessary if neither the primary nor intermediary were resorted to. Of the secondary operations there were a great variety, and he would not enter upon a criticism of their respective value. In the incomplete tear, where the vaginal ring had not been much involved, Tait's flap operation was expeditious and could hardly fail. Where there was prolapse of the posterior vaginal wall he used Hegar's colpo perineorrhaphy with slight modifications of his own. For complete perineal lacerations he used the same author's method with slight modifications.

Old Ideas with a New Dress.—DR. THOMAS ADDIS EMMET said that apparently the author had given a great deal of study to the subject, but he must confess that from his stand-point he seemed under the influence of the older teaching, when men were misled in speaking of a perineal body. He believed that, until we dismissed the idea of a perineal body entirely we would not be able to understand the condition of things present in lacerations at childbirth. We should simply bear in mind the presence of a diaphragm which closed the floor of the pelvis, and exclude the term perineum. The so called perineum was simply a part and parcel of the muscular septum, with the addition of a little extra fat which lay between the rectum and vagina, and which was of little or no consequence. He would confine his remarks to the levator ani muscle, the transversus perinei, and the fascia. First, we must consider what was a laceration of the perineum. He believed the perineum was never lacerated except the sphincter ani was torn to begin with. It was an injury to the fascia in the pelvis which allowed the muscles to separate, the fascia to retract, and the final result was one of imperfect support of the blood-vessels in the pelvis. They became over-distended, and caused great suffering in walking. We had been taught that the perineum in some way or other supported the vagina and uterus, but to his mind this view was as absurd as would be the statement that the pantaloons were held up because they rested on the instep. It was a mechanical absurdity. The uterus was suspended, as was every organ in the body, from above. If it had only support from below the woman would not be able to walk at all. Twenty-five years ago, or more, he witnessed some dissections of the pelvis at Edinburgh which taught him the necessity for doing something more than simply bringing the vulva together in these cases of laceration.

The sulcus of the vagina posteriorly was formed of fascia continuous with the pelvic fascia above, which kept the posterior vaginal wall against the upper or anterior vaginal wall, the latter being as fixed, to all intents and purposes, as the roof of the mouth. Anything entering the vagina or passing out must do so by pushing back the posterior wall as it would the under jaw if it were a bolus of food. This fascia, which ran down alongside the vagina, and was in close connection with the tissue of the pelvis, was also reflected over the muscles at the vaginal outlet, bound them together in one common sheath, as it were, and passed over and fixed the neck of the bladder under the pubis. The muscles forming the pelvic diaphragm did not cross one another, but were kept together by the fascia. The head of the child coming down like a piston in a barrel, exerted force upon the posterior curve of the vagina, met resistance by the fascia binding together the muscles, and the first result when injury took place was separation of the fascia binding together the muscles on each side of the vagina.

That part which was called the perineum served no purpose beyond that of giving proper support to the sigmoid curve of the rectum. When it was torn apart in the manner just described the anus was drawn farther back toward the coccyx, the sigmoid flexure became exaggerated, forming a rectocele, and then a cystocele came with it. The direct result of this was engorgement of the blood-vessels which should get support from the connective tissue. When the woman had remained a long time in this condition it became impossible to clear the vessels, and they became great receptacles for blood.

He repeated that when the perineum was injured the tear began far back by the rectum, long before it reached the vaginal outlet, or where there was any body or fourchette. That he was correct in his view was shown by the fact that where there was only a tear in the so-called perineal body, directly in the median line, the woman did not suffer; she could go on working at the washtub, and found no inconvenience except from want of control of the fæces. The blood-vessels had not been injured or deprived of their natural support. The worst tears were often unaccompanied by any lesion of the mucous membrane or integument at the fourchette.

Dr. W. M. Polk remarked that there seemed to be a greater difference of opinion regarding this little body than almost any other of equal importance, and he inferred from that that there was yet a great deal to be learned about it. He had constructed a theory of his own, which seemed to be the privilege of every man who had to do with this region. From a surgical stand-point, he thought most theories regarding the perineal body took into consideration too many elements, which lent obscurity. He thought that if we looked upon it as a diaphragm limiting the lower part of the abdominal cavity, it would do a great deal toward simplifying the question. If we regarded it as possessing the same relations to the abdominal contents as other portions of the abdominal walls, namely, serving to maintain them in their normal relations, he thought we would have gained a better appreciation of its function and the necessity for its repair. When it gave way, we had a hernia, and nothing more. This should be viewed as one would view a hernia in any other part of the body. For practical purposes, he thought we could ignore everything except the levator ani muscle and the fascia belonging to it. It was an important fact, as previous speakers had stated, that this muscle could be separated without any very prominent external lesion. The question of repair was simply one of restoring the structures as nearly as possible to the condition which they were in before the injury. He thought we could do no better than follow the same principles which applied to hernia in other portions of the abdomen. If the immediate operation could not be performed, he thought little of the intermediate, since retraction of the tissues took place even within forty-eight hours. In the secondary operation he followed the principles involved in Tait's operation and Marcy's method of Boston, bringing together successive layers of torn structure as nearly as possible.

Dr. W. Gill Wylie joined Dr. Emmet in criticising the paper as seeming to take the old view when speaking of a perineal body. It seemed to him Dr. Emmet's illustration of the separation of a curtain was much more appropriate than to talk about a body in the centre, called the perineal body. He had expressed the view in a paper six years ago that the levator ani was the important part, and if an immediate operation could be performed, almost anyone of the usual procedures would do, but greater difficulty existed after atrophy had taken place. He thought the prolapsus of the rectum was due to pressure of fecal matter, and with it there followed displacement of the uterus. He had described his method of operating many years ago, the important feature of which was to restore the sphincter ani and throw back the rectocele.

Dr. A. F. Currier bore in mind the principle in treatment to restore the parts, as far as possible, to their normal relation, and, in general, Tait's operation fulfilled this indication better than any other.

Dr. Buckmaster thought Dr. Wylie had to some extent put the cart before the horse when he stated that Dr. Emmet considered the rectocele was due to over-distention of the blood-vessels. Dr. Emmet considers this condition of over-distended vessels to be due to the tearing loose of the fascial sheaths which hold the muscles of the pelvic floor in place and support the connective tissue, which in turn supports the blood-vessels.

As to the tissues involved in the injury the following experiment will help to make this matter clear. The rectum of a multiparous woman felt through the vagina appears not unlike a segment of thick rubber tubing. The only cause for this rigidity is the fascia which is reflected from the levator ani sling to its sides, and bearing this in mind the tears can be readily recognized. We have given up trying to obtain a firm abdominal wall by the union of the muscle after a laparotomy because to expect muscle to sustain continuous strain is not only opposed to physiology but because we have found practically that no muscular support is of any avail without a backing of fibrous tissue.

Having recognized the many degrees and kinds of injury he believed the so-called Tait's operation a poor method of repair. He claims among its special advantages that no harm is done if it fails. The writer had seen a woman, where the operation had failed, with two large sulci (the remains of the incisions) that allowed everything to fall away. The denuding operation can be repeated as well as this flap splitting. The Tait operation crowds back a lot of tissue which atrophies, and the method is a clumsy one compared to that of Emmet, which when done intelligently will meet every indication that can be met which arises from injury to the pelvic floor. All operations will fail to cure a limited number of cases.

Dr. Garrigues closed the discussion. He thought that instead of representing the old time teaching, he represented a newer time than Dr. Emmet's. It was true Dr. Emmet had called attention to the importance of the tear at the vaginal ring, but he attributed the lesion to a tear of the fascia, and he had repeated this evening again that when the levator ani was broken it was the fascia which had torn apart. This, in the speaker's opinion, was a mistake. The fascia was a hard connective tissue, with scarcely any elastic fibres in it, and would be the last to tear apart, whereas it was an inherent quality of muscular tissue to retract when it was torn. He claimed that the tear was in the levator ani muscle, that it almost always took place in a longitudinal direction. We could not readily drop the anatomical terms perineum and perineal body. He had never said the uterus should be held in place by this body; it was well known to be held by the uterine ligaments. It was going too far to say the perineum was never torn except the levator ani were torn, for while he had placed great stress upon the importance of the latter, yet he had been able to demonstrate its entirety in one case in which the partition was torn to such an extent that a rent could be felt an inch and a quarter up the rectum. It was important to recognize the fact mentioned by Dr. Currier that one could not unite structure to structure exactly when they had long been separated. We must bring together what we could, yet the result could not be compared to that following immediate repair.

SECTION ON GENERAL MEDICINE.

Stated Meeting, February 17, 1891.

Francis Delafield, M.D., Chairman.

The Value of Subcutaneous Administration of Gold and Manganese in the Treatment of Tuberculosis.—Dr. John Blake White read a paper on this subject, a report of which appears on page 338.

Dr. James R. Leaming said there was plenty of room for work in connection with the treatment of phthisis,

and he welcomed all honest efforts in this field. We were still waiting for more light, and we certainly needed all that we could get.

Dr. S. Henry Dessau said that he had seen some of Dr. White's cases, and from one of them particularly he had had the personal testimony of very decided improvement in a short space of time. The method advocated by Dr. White had excited much attention in another society to which both Dr. White and himself belonged, and all its members were watching with much interest for the report of further results. It was only fair, it seemed to him, that the plan should be given a trial for a sufficient length of time to enable one to form some estimate of its real value.

Dr. Henry S. Harris said that while he was on the same service at Charity Hospital as Dr. White, and had seen most of his cases, he had himself had the opportunity of trying this treatment in only one case, and that was one which was not at all well suited for injections in any way. The patient was a female, and on January 7th he made the first injection with one drop of a two per cent. solution of chloride of gold and iodide of manganese. The only improvement that he had noticed was a slight gain in weight, and when he made an examination of the patient to-day he found that the area of disease had rather increased than diminished since the treatment had been commenced. Still, she stated that she felt better, and that both cough and expectoration had diminished. The conditions under which the woman was living, however, were so unfavorable as to make her case a very unsatisfactory one in which to make trial of the method. In Dr. White's cases he had personally noted the general improvement which had been described in the paper.

Dr. Grinnell said, that while he was more familiar with the Koch treatment than with Dr. White's, he had had some experience with the latter. Up to the present time, however, he had not been impressed with the great value of either one of these methods, though it was, of course, desirable to have a more extended series of observations before arriving at any definite conclusion.

The Chairman said that one seemed to be still as much in the tentative stage of the treatment of tuberculosis as ever. He was therefore always glad to hear of conscientious work in any new direction, and he trusted that Dr. White would go on with his investigations until the method advocated by him had been thoroughly tested.

Dr. W. C. Jarvis said that he could vouch for the correctness of Dr. White's statements in regard to the remarkable manifestations seen after the gold and manganese injections. This reaction closely resembled that observed when the Koch method was used, and it was the opinion of the House Staff at Charity Hospital that it was difficult to distinguish between the two. The improvement in some of Dr. White's cases was marked, and the effects of the treatment, he believed, were not in any way excelled by those of the Koch method.

Dr. White, in closing the discussion, said that the treatment described he advocated not as a specific for tuberculosis, but as an adjuvant to other treatment. In connection with this remedy, however, he believed that other treatment would be found to be more advantageous. Up to the present time he had seen no bad effects whatever from the use of his injections, and there had been no case of abscess or any serious local irritation resulting from them, although some of the patients had received as many as twenty-eight or thirty injections.

Cough: Its Uses, Significance, and Indications.—Dr. James R. Leaming read a paper on this subject which appears in full on page 336.

Hot claret is said to be an excellent gargle in acute sore throat, being an agreeable astringent and non-poisonous.

Clinical Department.

NOTES ON "ACID DYSPEPSIA."

By GEORGE HASLAM, M.D.,

FREMONT, NEB.

It is no uncommon occurrence for a patient to consult his physician for "acidity of the stomach." Such patients are usually young or middle-aged adults who otherwise enjoy perfect health. On questioning the patient one learns that many of them can overcome the "heartburn" by taking a small portion of food, and that the relief thereby afforded lasts for a longer or shorter period, varying from a few minutes to an hour or more; others obtain temporary relief by the use of various alkalies. Such symptoms are frequently accompanied by constipation, but sometimes by a slightly relaxed condition of the bowels. It is very seldom that such a patient is emaciated. On the contrary, he frequently has the expression and color of perfect health. In such cases the stomach-contents were found to be very acid, and to contain an excess of hydrochloric acid. Gastric digestion was, in the majority of cases, well and quickly performed, but after the food had disappeared the stomach still contained a larger or smaller quantity of a clear, slightly mucous, very acid fluid.

On thinking the subject over I concluded that the symptoms were due to an excess of hydrochloric acid being present, and reasoned that if the hypersecretion of acid could be inhibited most of the distressing symptoms might be prevented. It then occurred to me that by stopping the supply of sodium chloride this object might be attained; this conclusion was further strengthened by finding that many such patients were in the habit of indulging very freely in table salt. My experience with many cases confirms this conclusion; cases of long standing have been perfectly relieved by simply abstaining from salt, that is, they ingest no more than is supplied by the ordinary cooking processes.

Such cases being always office patients I have been unable to investigate the fæces. I am, however, inclined to the opinion that in such cases as are attended with laxity of the bowels the acids of the stomach are more than sufficient to neutralize the alkaline secretions of the pancreas, liver, and small intestine. As far as I am aware, abstention from salt has not been previously recommended with the object of directly influencing the secretion of the hydrochloric acid, the prohibition of condiments being recommended merely on general grounds.

It may be answered that "acid dyspepsia" is due to the presence of lactic, butyric, and perhaps other organic acids produced by bacterial fermentation. I can so far only reply that these remarks are the results of a clinical experience, and that no treatment, including lavage with antiseptics, has given any other than very temporary alleviation. Again, it can by no means be definitely stated that such organic acids have no other than a bacterial origin in the stomach; it is still possible that they may be produced by unformed ferments or otherwise. Lastly, it may be suggested that as the free hydrochloric acid of the stomach is probably formed by the action of lactic or other organic acids on the sodium chloride within the parietal cells, consequently these organic acids are the original cause of the excess of the hydrochloric acid. Granting this, we cannot regulate the formation of these acids, and it still remains possible that in some manner Na Cl, or its derivatives, may stimulate or cause the partial formation of such acids.

It is, I believe, very evident to all practitioners that our knowledge and classification of stomach "catarrhs" or "dyspepsias" are still very imperfect, and by no means cover the ground. I am inclined to think that in the cases described the only parts of the mucous membrane at fault are the parietal cells of the fundus glands, and that here we have to deal with a pure "acid dyspepsia."

TREATMENT OF BALANITIS.

By W. R. CHICHESTER, M.D.,

NEW YORK.

In cases of balanitis one of the most potent causes for a continuance of the inflammation is the decomposed accumulation of the sebaceous material exuding from the follicles in the furrow at the base of the glans penis—mucus, pus, epithelium, etc.—which acts as a direct irritant. Assuming that the symptoms of this inflammation are well known, I wish to indicate a plan of treatment which has, during the past ten years, proved itself highly beneficial, and of which I can find no mention in medical literature. I refer to the local application of sulphate of atropia, the physiological action of which suspends the function of the mucous membrane and its glands when directly applied to the parts. This agent, combined with a mild astringent and a deodorant, gives us a means of absolutely controlling the secretions, at the same time it meets almost all other indications in treating the inflammation. The sedative action of atropia will relieve the tenderness of the parts, or if the pain is severe it can be combined with cocaine. The danger of systemic effect is almost nil; and should this follow, a suspension of treatment for a short time would suffice, when the solution may be reapplied at longer intervals. Where phimosis exists, a few drops of the solution may be injected between the glans penis and prepuce, with a slender-nozzled syringe, after the parts have been properly cleansed, and it will be found that the discharge will either immediately cease, or be greatly modified, affording us a point of diagnostic value in cases where urethral gonorrhœa is simulated. The ordinary advice to patients to keep the parts clean and dry cannot always be followed faithfully, and we can obtain better and quicker results if we take advantage of the peculiar action of this drug. Even in patients whose prepuce is long, and the mucous membrane lining it and covering the glands is sensitive to irritation, an occasional application of these combined agents will, in a very short time, render the part much less liable to inflammation. The subjoined solution is the one ordinarily prescribed by me, although it is open to any modification that the case suggests:

℞. Atropiæ sulphatis..... gr. j.
Zinci sulphatis..... gr. ij.
Acidum boracicum..... gr. v.
Aquæ destillat..... ℥ j.
M. Sig.: Apply twice or three times a day with a small brush.

13 WEST TWENTY-SIXTH STREET.

A CASE OF ENTERIC FEVER WITH PECULIARITIES.

By JOSEPH COLLINS, M.D.

Although physicians do not expect to find cases of enteric fever presenting the symptomatology of their textbooks without some irregularities in its development, it is rarely, I think, advisable to publish reports of individual cases; but the following case presents so many radically different features from the ordinary disease as to make it worthy of record.

Mrs. F——, aged fifty, complained on Monday, January 19th, of feeling somewhat indisposed and exhausted, but attributed it to the labor of a heavy wash-day. The next morning she had a headache, pains in the back and limbs, and chilliness, and that night a distinct chill lasting about six hours, followed by fever but no perspiration. The next day I was called in to see her and found her with a temperature of 103° F., a rapid compressible pulse, dry, furred tongue, some nausea and inability to keep anything in her stomach, bowels constipated, no abdominal tenderness or disturbance, urine about twenty-eight to thirty ounces in twenty-four hours, febrile in character, but containing no albumin. Face somewhat turgid but denoting no anxiety, pupils contracted, and mental condition rather sluggish, as she cannot tell exactly how she is sick, except that she has a splitting pain in her head, and it extends down her spine and her legs feel heavy and dead, and when attempting to get out of bed she staggers. Does not think she is very ill and wants to be left alone.

The following day, Thursday, there is no apparent change in the symptoms, except that the fever has been continuous and is now a trifle higher, 103.5° F., and her mind less responsive. On Friday the family report that she has been quite delirious during the night, attempting to get out of bed and not recognizing her own children. The symptoms are all exacerbated except the temperature, which remains the same.

Saturday morning I found an eruption on the chest and abdomen, and this seemed to be of two different varieties. One was irregular in form, purplish in color, seemingly not elevated, and disappeared on firm pressure, and then quickly reappeared; these spots were quite numerous, and varied in size from a pin's-head to a spot half as large as a penny, formed seemingly by the coalescence of several smaller ones. The second variety of eruption consisted of very small, bright-red spots which filled in the spaces between the others, and these were mainly on the abdomen; they were not elevated, disappeared on pressure, and recurred slowly.

Later in the day she was seen in consultation by one of the ablest consultants in the city, who gave it as his opinion that the case was unquestionably one of typhus fever. His diagnosis being based on the onset of the disease, the headaches and pain in the spinal regions, the temperature and early presence of delirium and prostration, and particularly the eruption and the absence of diarrhœa, abdominal distention and gurgling in the iliac fossa. On Sunday she was seen by Dr. Cyrus Edson and the Chief Inspector of Contagious Diseases, with a view to her isolation, and in a note to me later in the day Dr. Edson says that undoubtedly it is a case of marked enteric fever with unusual phenomena, giving as reasons for his diagnosis the absence of typhus fever in New York unless imported, for the past six or seven years, and the fact that the patient had not come in contact with any newly landed emigrants, or otherwise been exposed to any possible infection, and that no other member of the family had shown any signs of contracting the disease.

On Monday the eruption began to fade, the temperature still continued hovering about 104°F., the pulse very small and rapid and irregular in its force; the general condition of the patient being very bad. And this lasted till Friday, when the temperature fell to normal, where it remained, with the exception of an occasional rise of a degree in the afternoon.

From this time onward there was slow but continued improvement, so that in the latter part of the third week of her illness she was entirely convalescent.

The treatment employed was that which perhaps commends itself most favorably to physicians to-day, and consisted in the early and continued administration of intestinal disinfectants, as diluted hydrochloric acid, bismuth and charcoal, and stimulants as they were indicated.

Of course the radically different points in this history from that of the common case of enteric fever are the peculiar eruption, which really corresponded with the one ordinarily given for typhus, and there was no recurrence of it as in crops after it had first faded. Then the sudden rise and continued temperature, the constipation, the prolonged chill and prostration, the lancinating headache and early occurrence of delirium are not common symptoms of typhoid fever.

Methyl Blue in Diphtheria.—Dr. H. Beyer, of Stapleton, N. Y., writes to the *Medical News* that he has used methyl blue in fifty cases of pharyngeal diphtheria with successful results in all cases. He applies a mixture of chemically pure methyl blue and sugar, 2 parts to 98, using it as a powder.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ADJOURNED DISCUSSION ON REMOVAL OF THE VERMIFORM APPENDIX—MR. KNOWSLEY THORNTON ON HEPATIC SURGERY.

LONDON, March 7, 1891.

At the last meeting of the Clinical Society the discussion on removal of the vermiform appendix was resumed by the President (Sir Dyce Duckworth), who remarked that it was a question of moment for the physicians to decide when to transfer these cases to the surgeons, and for the latter to determine how best to conduct the operation. It was evident that operation was not needed in every case.

Mr. Langton said that the results which had been brought forward showed that removal of the appendix did not necessarily involve any serious risk to life. Though he had seen a large number of cases recover under the care of the physicians, he was sure that surgery was far in advance of medicine in the treatment of this affection. In the cases of acute perforative appendicitis, especially if associated with general peritonitis, operation was clearly called for at once. In recurrent cases, with a periodic rise of temperature, indicating probably the formation of a small amount of pus, interference was also justifiable, but a considerable number of cases remained in which it was difficult to decide. It was bad practice to thrust in a needle to search for pus, and it added considerably to the patient's danger.

Mr. Pearce Gould said he could not agree that surgeons were at one with regard to methods of treatment. The relapsing or recurrent cases formed about ten or eleven per cent. of the whole, and those with general peritonitis about a similar ratio. But by far the largest number of cases were instances of inflammation of the appendix associated with circumscribed suppuration. Mr. Sutton had seemed to imply that abscess had existed some time before the acute symptoms were set up; but, for his own part, he regarded the abscess as the result of the local disease. The inflammation which occurred round the appendix very often not only shut off and localized the disease, but set up an inflammation in the appendix itself, which led to its obliteration, and the patient might then remain free from attacks afterward. He had never known a relapse after an attack of suppurating appendicitis. As to the treatment of these cases, the abscess should be opened, washed out, and drained, but the appendix need not be removed. It was better to wait in order to see where the abscess was forming, and then evacuate the pus by a small incision not more than an inch or an inch and a quarter long. This not only weakened the abdominal wall less, but one could never be sure of the extent of the adhesions, and it was certainly desirable to avoid opening the general peritoneal cavity. All the pouches of the abscess should be opened, taking care to avoid breaking down the limiting adhesions. He was glad to learn that Mr. Treves's opinion in regard to the desirability of removing the appendix in cases of relapsing typhlitis was different from that he had put forward three years ago. It should not be forgotten that there was a distinct mortality to this operation. Error in diagnosis was also frequent, and he had himself seen one case in which a perfectly healthy appendix was found on exploration.

Dr. J. K. Fowler said Mr. Treves was apparently now of opinion that in the majority of the cases which recovered the symptoms were due to fecal accumulation in the cæcum, followed by stercoral ulcer and inflammation of the overlying peritoneum. Stercoral ulcer, however, was a rare condition, generally absent in fecal accumulation, far in excess of that met with in typhlitis, and when present, as in chronic obstruction of the large bowel, often the cause of perforative peritonitis, whereas in fatal cases of typhlitis no such changes were found in the cæcum. All the evidence was in favor of the appendix being the seat of the affection. That the complete clearing up of the local signs could not be trusted to prove that the mild cases were of cæcal origin was shown by a case of Mr. Treves's, which proved to be one of appendicitis although before the operation there was "no trace of the iliac swelling," and "the abdominal signs had entirely disappeared." He agreed with the statement that "it could not be denied" that inflammation of the cæcum might in some cases be the cause of the symptoms, but he knew of no evidence pointing to that conclusion. During ten years eighty-five cases had been admitted into the Middlesex Hospital with the diagnosis of typhlitis or perityphlitis, and of these eighty-four had recovered and one had been "discharged at her own request." Only two of the cases had been submitted to incision. These figures showed that "the measures generally employed by physicians were not without success." During the same period the appendix was found, on necropsy, to be perforated in fourteen cases; in none of these were the signs during life sufficiently definite to allow of a positive diagnosis of typhlitis. No absolute rules could be given as to when to operate in such cases, but he thought the persistence of a high temperature after the fifth day suggested suppuration.

Mr. Charters Symonds related a case of his own in which a concretion was found in the appendix. He agreed with Mr. Gould that it was usually not necessary to remove the appendix, and referred to three cases in which, after simple opening of the abscess, the patients recovered. The abscess should be thoroughly irrigated out and a concretion sought for, due care being taken not to disturb the adhesions.

Mr. Jessett considered that the cases which the authors had related showed that early operation must be a proper procedure; the risk to life was certainly not so great as if the diseased appendix was left behind. If an abscess formed which was shut off from the peritoneal cavity, then the appendix might be left. In dealing with the stump of the appendix he suggested that it should be invaginated into the cæcum and held there by stitches.

Messrs. Allingham, Bland, Sutton, and Andrew Clark then replied.

At the Medical Society's last meeting a paper by Mr. Knowsley Thornton was read, entitled "Observations on some Additional Cases Illustrating Hepatic Surgery." The author gave notes of nine cases in which he had diagnosed gall stones. In seven of these he had found the gall-stones and removed them with complete cure; in one case he failed to find the stone, which (the patient dying) was found after death in the peritoneum; in the remaining case hydatids were found to be the cause of obstruction, and the patient recovered. Seven other cases were then referred to in which he had operated. One of these was a large hydatid cyst of the liver, which had been diagnosed by several physicians as disease of a much more serious character; the patient recovered. Two were cases of malignant disease, one a case of doubtful nature, and one of chronic pain and adhesion after the passage of large gall-stones. In none of these did he consider that the indications before operation pointed to the presence of gall stones. In one other case he operated, expecting to find gall stones; but found nothing definite to account for the attacks of pain, and though temporary relief followed the exploration, there had been recently fresh attacks of pain. The last case was one of very large tropical abscess of the liver, in a gentleman aged sixty five, in which unusually rapid recovery followed free incision and drainage. Mr. Thornton claimed that the results as a whole justified the operative procedures. At the same time there was sufficient uncertainty and failure to show that it was to more perfect diagnosis our attention must be directed. This would be aided by more frequent exploration in doubtful cases. Mr. Thornton pointed out the danger of attempting to force the stones through by massage. He also drew at-

tention to adhesion of the gall-bladder to the right kidney as a source of error in diagnosis, both from the position of the swelling and the sympathetic renal symptoms induced. He claimed three entirely new departures in this branch of surgery: 1. Direct incision of the common duct and removal of the stone, with complete suture of the opening without opening the gall-bladder. 2. Incision into the common duct, needling the stone into fragments, and closing the duct over the fragments, which were left to find their own way into the duodenum. 3. Leaving the gall-bladder open in the peritoneum, with efficient provision for drainage through the abdominal incision in cases in which it was impossible to suture it into the abdominal wound, and not advisable to attempt complete intra-peritoneal suture. In the latter case, and in all cases where fouling of the peritoneum was possible, he strongly advised a counter-opening above the pubes, and additional drainage by means of a glass tube in Douglas's pouch.

SURGERY BY AID OF ANODAL DIFFUSION.

To the Editor of the Medical Record.

Sir: In your issue of January 31st appears an interesting article upon "Anodal Diffusion," by Dr. Frederick Peterson. In it he quotes from a note received by him from me in June, 1889, the following sentences: "I have recently, since reading your article, tried this method upon a child's hand, requiring suture of a severed tendon. The injury was an old one, and there was no wound before I made my incision. The anæsthesia from ten per cent. cocaine upon the anode, continued with my chloride of silver battery (twelve cells) for ten minutes, was very satisfactory."

I write you, sir, to correct an error. My note aforesaid was written very hastily, and not *ten* but *twenty* minutes should have been the time mentioned; as appears from my history-book. I correct this misstatement, since others may try it, and will not, I am sure, feel satisfied with the anæsthesia produced in ten minutes; unless, indeed, a much larger number of cells than twelve be put in circuit. Furthermore, while I did not entirely shut off the circulation, yet by elevating and "milking" the limb and then holding it elevated during the anodal diffusion, I prevented in great measure the penetrating cocaine from being swept away in the blood-current. This should have been mentioned in my note to Dr. Peterson.

For ordinary purposes of local anæsthesia in surgery the element of time will always prevent anodal diffusion from supplanting other and quicker methods. Cocaine by hypodermic needle, freezing by ether spray (or on wet days, better, by æther petrolii), in each case with maintenance, of course, of local anæmia by tight rubber tubing or Spanish windlass—these plans are as efficient, and much more prompt. There are instances, nevertheless, wherein the electrical method of introducing cocaine serves an excellent purpose, hard of accomplishment otherwise. For instance, I have repeatedly used it, to the patient's satisfaction, as a preliminary step to removal of superfluous hair from the face by the electrolytic needle.

Very respectfully,

Robert H. M. Dawbarn, M.D.

345 West Fifty-sixth Street, N. Y.

METHYL BLUE IN MALIGNANT INOPERABLE GROWTHS.

To the Editor of the Medical Record.

Sir: At the last meeting of the German Physicians, on February 27th, I took the opportunity of referring to several experiments done by me with methyl blue. While I postpone reference to the subject in full for some later occasion, I would like to call attention to the following statement:

"Since February 2d, Dr. Rudish and I have administered methyl blue internally (by the mouth or rectum) in malignant inoperable tumors. The first case on which this method has been used by us refers to a lady about forty years of age, suffering from cancer of the uterus and ovaries; the condition before February was most critical, the tumor was as big as a man's head; anasarca, œdematous swelling of both limbs and the whole body, reaching nearly to the shoulders. The patient could hardly eat anything, the pulse was usually varying from 110 to 120, and very weak; pains, constantly. After giving methyl blue 0.2 in capsules, first by the mouth and afterward by the rectum, one capsule every day, the patient after a few days began to feel better; she lost her pains and could partake of more nourishment; in three weeks the anasarca disappeared, likewise the œdematous swelling, and there was noticeable a decrease in the circumference of the tumor. The pains have left entirely, the patient sleeps and eats, and is in the best of spirits; pulse, 80. The change in this patient's condition is a remarkable one. Two other cases of cancer (one of the stomach, the other of the liver) are undergoing the same treatment in the Mount Sinai Hospital, under Dr. Rudish, but the methyl blue has been given here only a short time. As this method of administering methyl blue internally (even not by means of hypodermic injection) was used first by us (Dr. Rudish and myself) in cases of inoperable malignent growths, and, as shown above, with seemingly good results, I take pleasure in recommending this method to the medical profession. The methyl blue must be chemically pure, and can be given in doses from 0.2 to 0.3, once or twice a day. The methyl blue can be had of Eimer & Amend (corner of Eighteenth Street and Third Avenue). I have used methyl blue also in cases of cystitis and pyelitis, and in phthisis pulmonum, but at present I have not as yet formed a firm opinion as to the value of methyl blue in these affections. Very sincerely yours,

Max Einhorn, M.D.

120 East Sixty-fourth Street, New York.

SCARLET FEVER IN JAPAN.

To the Editor of the Medical Record.

Sir: Enclosed you will find a letter, or rather a paper, which some time ago I sent to Professor James Law, with the request to publish it in your journal with the notes of the Japanese case of scarlet fever at Cornell, doubtless the same case recorded by Dr. Kirkendall in your last issue. I had done this upon receiving a letter from Professor Law, giving me all the details of that case. The following is a copy of what I wrote to the professor.

Sincerely yours,

Albert S. Ashmead.

4 King Street, New York, February 21st.

(*Copy.*)

Professor James Law, Ithaca, N. Y.

Dear Sir: I thank you for your letter of the 22d inst., with its interesting information relative to a case of scarlet fever in a Japanese student at Cornell. As you say, it may serve to throw light on the question whether susceptibility can be acquired by acclimation. There are three diseases prevalent in Japan with which Japanese cases of scarlet fever might be confounded: measles, roseola, and red measles or rubeola, the last very different from the first. The first appears in Japan only in epidemics and at long intervals. During my service there I saw none at all. In 1876 and in 1882 such epidemics are said to have occurred. Between these dates no cases were observed in Tokio. Baelz speaks of this disease as follows:

"The measles have been long known in Japan, and appear, as in other countries, occasionally in the form of a great epidemic. But these epidemics are rare, so rare that often a large portion of the population presents no cases at all for a long time. The last great epidemic occurred twenty years ago (1862); almost all now adult

Japanese of twenty to forty years of age were at that time sick of the measles; the same had happened to the older people twenty years before. It is believed that every twenty years a great epidemic is to be expected. In the intervals small endemics and isolated cases are said to be frequent. However, I have not seen, between the years 1876 and 1882 one single Japanese sick of the measles, and besides, a confusion with the rubeolæ (*sic*), of which anon, is not improbable. Among the children of the foreigners in Yokohama and Tokio the measles have been positively observed."

There exists in Japan another disease which the natives call kosahana (wind blossoms), which foreign observers variously term roseola, rubeola, and red measles, and which has been frequently mistaken for scarlet fever. It is not even allied to scarlet fever. It is an incontrovertible fact that puerperal fever does not exist in Japan; also that the presence of kosahana in a lying-in room does not result in the infection of the puerperal woman. These facts, I think, prove the non-identity and non-congeniality of kosahana and scarlet fever.

Remy, in this connection, says: "We meet with an exanthema offering now the symptoms of scarlatina, now of measles, appearing epidemically, often without fever, sometimes without subjective symptoms attracting the attention of the patient. The conjunctivæ, the throat, the vail of the palate, the pituitary, the bronchi, are slightly affected; there is a furfuraceous desquamation, almost imperceptible. Dr. Baelz calls it rubeola."

Here are some observations of Baelz on the subject: "Rubeola (red measles) is an exanthematous disease popularly called kosahana, that is, 'wind blossoms,' which has been long known in Japan. According to the descriptions the course of the disease is such a light one that often the patients take no notice of it at all. The exanthema is said to have some resemblance to scarlatina and often to measles. This suggested rubeolæ. In 1882 I was able to show that kosahana is nothing else. There was at that time a wide-spread epidemic in Tokio, and I had occasion to observe a great number of cases. As this epidemic has been described more accurately in another place, the following short indications will suffice: The exanthema was sometimes more like scarlatina, sometimes more like measles, but was in most cases easily differentiated from both. Yet sometimes its difference from scarlatina was not so easily perceived. Fever was sometimes absolutely lacking; where it existed it hardly ever reached forty degrees. As a rule, the conjunctivæ presented a slight catarrhal affection, likewise the throat and palate; rheum and bronchitis existed in a slight degree. Never really severe angina; never nephritis. Desquamation in small scales, often very indistinct. Frequently all subjective symptoms were lacking so completely that the patients themselves did not suspect that anything was wrong with them. They almost never sought their bed. The majority of the cases were adults. The contagiousness of the disease is smaller than in measles, scarlatina, or small-pox. All the patients recovered. The epidemic lasted about five months; isolated cases appeared the year through."

This is the disease which some natives claim to be the scarlet fever of Japan. It will be proper, perhaps, to state here that Baelz, whose description I have just quoted, thinks that the real scarlet fever exists in Japan. "All those," says he, "who have written up to the present time on these questions agree that there is no scarlatina in Japan. Wernich says distinctly that scarlatina is as yet a phenomenon perfectly unknown in the Japanese islands. This is a delusion. The disease is rare, but it exists. In 1877, that is, before the book of Wernich was published, I had observed such characteristic cases of scarlatina that I could in every respect demonstrate them to students, especially in regard to the course of the fever, as regular types. Strangely enough, all these cases—nine in number—concern youths and men from the age of ten to that of thirty years. I have seen scarlatina neither in woman nor in child, though I have no doubt they also must be affected by it occasionally. Almost all cases happened at short intervals, but nowhere contagion could be clearly demonstrated. Of these nine cases one, complicated with severe diphtheria (?), died of heart weakness, the others recovered. Nephritis occurred once in a slight degree, as a complication. These last five years I have seen a small number of scarlatina patients—at the end of 1880 and beginning of 1881. At that same time there were observed in the city pretty numerous cases, which all had a favorable course. There may have been, however, some confusions with rubeolæ, which were rampant at the same time. My observations concern here the capital—Tokio—especially. As to scarlatina in other parts of Japan, I am in possession of no information."

Simmons, whose opinion I gave in the letter to the MEDICAL RECORD to which you refer, says further:

"Scarlet fever and cerebro-spinal meningitis have never yet made their appearance in this country. I am aware that this is denied by at least one foreign medical man, in regard to the former, who claims to have seen eight or nine cases of it; but if this is so how happens it that no one else has observed it? A disease so terribly infectious as scarlet fever could hardly be limited to the practice of one individual." Speaking of infectious diseases among foreigners, he says: "In fact there has not been a single case of small-pox, measles, or scarlet fever, in the town of Yokohama, among foreigners or natives, that has not been imported. Indeed, it is exceedingly doubtful if scarlet fever exists in Japan at all, except in a very mild form."

My own observations, which embrace nearly forty thousand examinations, in hospital and private service in Tokio, showed to me not a single case of scarlet fever, nor a single case of puerperal infection. It is clear that if a case of scarlet fever in my practice had been overlooked, puerperal infection would have called my attention to the fact of its presence. If scarlet fever does exist in Japan, as Baelz, almost alone of foreign observers, believes, then it seems that puerperal infection must occur also. This is not the case.

Climatic conditions may account for the fact that measles are not endemic, and for the existence of the wind blossoms, clinically so similar to our scarlet fever, though not possessing its virulent infection. But if, as seems probable, the Japanese have a peculiar power of resisting not only the contagion of measles and scarlet fever, but, in the case of the latter, of resisting even the blood inoculation of the germs, then, something else—a racial factor perhaps—must be assumed; or shall we admit that this pathological peculiarity of Japan—the absence of scarlet fever—is connected with that other peculiarity of the country, the absence of any intimate relation between man and cattle?

Yours very sincerely,

ALBERT S. ASHMEAD.

NEW YORK, January 23, 1891.

Opposition to Large Families.—Mr. Arnold White is much concerned that the working-classes have such large families. He is anxious that the begetting of children should be kept within reasonable bounds, and has been writing to *The Times* on the subject. He disputes "the title of a penniless man to marry, beget ten children, and leave the consequences to God." He would, in the first place, raise the age of marriage from twelve and fourteen to sixteen and eighteen; secondly, he would require a male minor desiring to marry to give proofs of his ability to maintain a family; thirdly, he would empower the clergymen and registrars to decline to celebrate marriages for reasons stated; and, fourthly, he would segregate until old age habitual criminals and paupers, so as to prevent the reproduction of their kind. The last proposition is one that we can all agree to fall in with. Habitual criminals, lunatics, and confirmed paupers are such undesirable characters that we should adopt any means short of manslaughter to blot them out.—*The Hospital Gazette.*

New Medical Society in Chicago.—The rumor has gone abroad that a new medical society is to be established in Chicago, owing—partly, at least—to the alleged insufficiency of the present organized bodies. It can be stated advisedly that, unless the new society is to take the form of a special body, it most certainly is a mistake, as there is now all the opportunity for professional association and advancement by the mutual interchange of thought that could well be desired. And even if it is the desire of any considerable number to have more attention devoted to any special branch such aim would best be accomplished by a sectional arrangement of one large society. The Chicago Medical Society now has a membership of quite five hundred, and is in a position to reflect upon any plan having the general welfare of the profession for its object.

Action of an Infusion of Coffee on Bacteria.—In studying the germicidal action of coffee Dr. Luderitz made use of infusions of different degrees of concentration, varying from five to thirty grains of coffee to 10 c. c. of water. He mixed from four to six drops of pure culture broth with 8 to 10 c. c. of this infusion, and at the end of a certain time he withdrew parts of this mixture and cultivated them in gelatine. Experiment showed that the micrococcus prodigiosus dies in a ten per cent. infusion of coffee in from three to five days, the bacillus of typhus in from one to three days, the proteus vulgaris in from two to four days, the staphylococcus aureus in from four to seven days, the streptococcus of erysipelas in one day, the bacillus of cholera in from three to four hours, the bacillus of anthrax in from two to three hours, and the spores of anthrax in from two to four weeks. In a thirty per cent. infusion of coffee the typhus bacillus dies in one day, the staphylococcus aureus in from one to three days, the bacillus of cholera in from one-half hour to two hours, the bacillus of anthrax in two hours, the spores of anthrax in from two to four weeks. In a second series of experiments Luderitz studied the influence of an infusion of coffee mixed with gelatine on the development of bacteria. These experiments showed that the micrococcus prodigiosus does not vegetate in gelatine containing from three to nine per cent. of coffee, the bacillus of typhus in gelatine with three per cent. of coffee, the proteus vulgaris with from five to nine per cent., the staphylococcus aureus with two per cent., the streptococcus of erysipelas with one per cent., the cholera bacillus with one, and the bacillus of anthrax with 0.6 per cent. The action is the same for the different qualities of coffee, and is due not to the caffein, but the products of the roasting of the coffee.—*The Sanitary News.*

The Baths of Damascus.—An old book tells the following story of a French doctor seeking a place to begin practice, which points out a valuable hygienic lesson: "A French doctor went to Damascus to seek his fortune. When he saw the luxurious vegetation, he said: 'This is the place for me: plenty of fever.' And then, on seeing the abundance of water, he said, 'More fever, no place like Damascus!' When he entered the town, he asked the people, 'What is this building?' 'A bath!' 'And what is this building?' 'A bath!' 'And that other building?' 'A bath!' 'Curse on so many baths! they take the bread out of my mouth,' said the doctor; 'I will get no practice here.' So he turned his back and went out of the gate again, and hied himself elsewhere."—*Annals of Hygiene.*

A Chicago Medical Library.—The medical profession of Chicago and vicinity will at no late day have abundant occasion to feel proud of the medical reference library to be placed at their disposal. Librarian Poole, of the Newberry Library—the large, new building for which is now undergoing construction—has been at no small pains to place himself in touch with the requirements of a grand medical collection. The representative members of the profession have been communicated with, and have been requested to furnish lists of such works as they wished to see placed upon the shelves. Already many productions of the utmost value are being gathered from far and near.

A Definition of Insanity.—Dr. Harris C. Rodgers, M.D., of Binghamton, N. Y., offers the following: "As a contribution to the elucidation of a problem which puzzles both the general practitioner and the alienist, I would offer, by the courtesy of the RECORD, the following definition of insanity, viz.: A disease of the brain exclusive of gross congenital and early childhood defect of development, which makes one's mental processes, under similar somatic conditions except for the influence of the brain disease present, differ from those of the great majority of people of one's generation."

Smart Sayings of Dunces.—A student taking the examination before the State Board of Examiners of Virginia for license to practise gave the following startling information: "Symptoms of œdema of the glottis are that the patient feels husky and has sore throat. I would amputate it if necessary. I would do the operation within three or four months if it was a bad case." That is about on a par with the man who said that in post-partum hemorrhage he would ligate the post-partum artery, or the one who thought that pyelitis was inflammation of the *pyloric end* of the stomach.

THE IMPROVEMENT OF EVACUATORS FOR LITHOLAPAXY, AND THE LATER DEVELOPMENTS OF THE OPERATION.

BY OTIS K. NEWELL, M.D.,

SURGEON TO OUT-PATIENTS AT THE MASSACHUSETTS GENERAL HOSPITAL, BOSTON, MASS.

WHEN Professor Bigelow, in 1878, first taught the world the value of litholapaxy, by demonstrating the toleration of the bladder to prolonged operation, he furnished what has been the greatest incentive to the improvement of instruments for the modern stone operation.

Nothing appeals more strongly to the mechanical sense of surgeons and the acquirement of delicate manipulative power than the construction and use of stone-instruments; and its history is as interesting, perhaps, as any chapter of surgery. I shall but briefly consider the development of evacuators up to the point of what I believe to be the best type among those thus far produced. It does not seem reasonable that an instrument which first began to be constructed certainly no further back than 1834 should yet have reached perfection; nor is it probable that advantageous change will not continue to be made until evacuators are no longer needed.

The development of evacuators is familiar to all. It began with Crampton's bottle, which was but a common ovoid glass flask with a stop-cock at its neck allowing the air to be exhausted. This was attached to a catheter introduced into the bladder and, with the stop-cock opened, drew the urine, in which were crushed stone fragments, into its vacuum. There was, in this bottle, no trap. The lithérétie of Cornay was a similar arrangement, and, according to Ashhurst's "International Encyclopædia of Surgery," was described one year earlier than Crampton's bottle. In this instrument, also, there was no trap, and as but one suction or pumping movement was made at a time, none was needed. Then came, with Mercier's washing bottle, and Clover's first evacuator, the various rubber-bulbed instruments into which a trap was introduced to admit of repeated suction movements. Without describing or criticising in detail any of these instruments, or any of the subsequent evacuators, I shall endeavor to show that in all of them two important factors in construction have been overlooked. First, that a trap is an unnecessary element introduced into the length of the evacuating canal. Second, that the surgical distance from the external meatus to the bladder is rarely more than from four to six inches, and that therefore the length of the evacuating canal through which fragments are to be lifted should seldom exceed twelve inches, and may range, in children and adults, anywhere from six to twelve inches, this including the total distance which fragments have to travel. The value of these statements to the welfare of litholapaxy is great, for it is important to increase its scope and diminish its mortality by every possible improvement of the instruments concerned in its performance. This is especially true for cases of stone in children; and where in adults, from large size of stone or other complication, the operation may be prolonged for even two hours or more. Notwithstanding the suggestion from many able operators, of recurring under the advantage of antisepsis more frequently to lithotomy by the supra-pubic way, I cannot but think, in consideration of the beautiful results of litholapaxy in children, that a stone will rarely be found whose removal shall depend upon the use of the knife.

In discussing the improvement of evacuators, I shall consider in detail those parts which have been radically changed in my instrument, and begin with the trap, which, whether as a form of valve or special receiver, has entered into the construction of all the other modern instruments.

The Trap.—That in a properly constructed evacuator a trap complicating and increasing the length of the evacuating canal is unnecessary can perhaps be best demonstrated by using my evacuator (Fig. 9). In this evacuator, as may be seen, the radical change is the introduction of a shortened tube into the top of the bulb.

Fragments of coal, coral, and other materials have been used by former experimenters in demonstrating the action of their evacuators; and although I have used all these, in order to be still more certain I have chosen fine sand for the crucial test. Now, it will be seen in operating the evacuator, that the sand fragments are rapidly drawn in by the aspirations of the bulb, driven against its top, and thrown into the receiver. They do not tend to float nor to be carried about in any swirl of the current, but in accordance with physical laws sink rapidly, and will be even seen to do so during compression of the bulb. In fact, so absolutely does the receiver, and the greater part of the bulb, for that matter, represent what Professor Otis, in describing his "perfected evacuator," has termed a dead point, that the grains of sand will be seen to settle quietly in a pile, the conformation of which will not be in the least disturbed by the most forcible compression of the bulb.

At the top of the evacuator, as in my first model, is attached the Bigelow pipe for filling. This I consider one of the most valuable parts of an evacuator, for by its use the volume of fluid in the bulb and bladder may be at any instant rapidly increased or diminished, and all air removed from the apparatus.

Tubes.—My second point for consideration is the evacuating tube, and in its construction we should bear well in mind what I have endeavored to lay stress upon in two previous publications, and that is the fact that the surgical distance into the bladder is usually not more than from four to six inches. By this I mean, and I have repeatedly proved the fact upon the cadaver and in the living subject, that if we take an ordinary curved metallic sound, introduce it well into the bladder, depress it to a plane parallel with the table, and then withdraw it until the curve arrests its further progress, we will, by pushing the glans as far back as possible upon the external portion of the instrument, find if we hold it at this point and then withdraw it, that only a few inches, three and one-half to six at the most, have been engaged upon what I am pleased to call the surgical length of the urethra, or the surgical distance to the bladder. This can be well shown by studying a figure from a frozen section made by me through a split metallic sound introduced and fastened in the position just indicated. The difference between it and the usual figures illustrating this subject is readily seen.

It therefore seems that in the construction of evacuating tubes we should endeavor to have them made so as to apply to the most advantageous length possible of use in each case. Why should we maintain a uniformity in

the length of tubes any more than in their calibre? I have seen a large number of cases in adults where evacuation could have been readily performed through a six-inch tube, while in others, as we all know, the evacuating power of the bulb has had to be diminished by very long tubes in order to overcome the difficulties of a prostatic

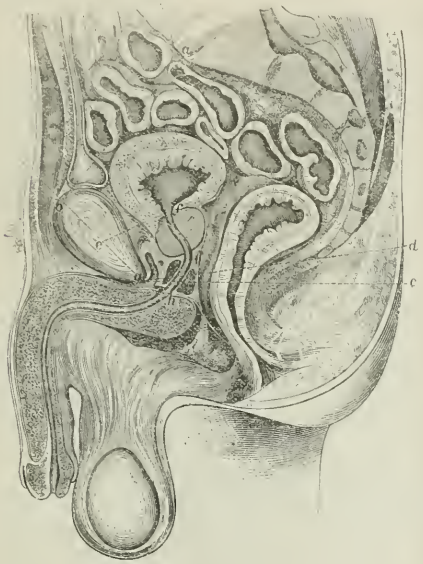

FIG. 1.—Taken from Dittel's Deutsche Chirurgie.

obstruction. In a delicate operation like litholapaxy, it does not seem wise to restrict ourselves to a limited and fixed set of tubes.

The more I become experienced in the use of straight open-ended tubes, the more I am convinced of their great superiority over any other kind. Given a bladder fully distensible and without inordinate prostatic obstruction, their action is perfect. One soon learns, using a tube that moves freely in the urethra, to place the tube orifice with the utmost precision and delicacy. By a few gentle aspirations the bladder wall can be felt almost as delicately as with the finger, and then the tube orifice placed in any desired position. Through these tubes the fragments travel in a straight line, and thus may be rapidly shot into the bulb. If the obliquely-cut opening be held laterally, the side of the tube may be then used to press against the bladder-floor. With the taper joints by means of which the tubes are connected in my apparatus, the orifice may be readily turned in any direction without uncoupling the apparatus. The floor of a distended bladder is not very easily aspirated, nor is the wall, for that matter, when the distention is even and full. With the orifice turned downward and held about one-fourth of an inch from the bladder-floor, the aspiration is very rapid. In fact, with the straight tube orifice carefully placed in any of the positions, lateral, upward, or downward, the aspiration is very rapid and certain. The fragments are shot in a straight line into the evacuator, and once there never return. I have had some operators, after using these tubes, say that after three or four aspirations there seemed to be something the matter, as no more fragments came. The fact, however, proved to be that they had all been removed, as the tubes were in the two cases in mind of 30 calibre. My straight tubes are constructed so that those of a given calibre take much larger fragments than can be passed through unguiform-tipped tubes of the same size. This is especially the case with those used in children, 17 F and lower calibre, where the advantage of the straight open-ended tubes is so great as to make the operation feasible with them, where it would otherwise not be. Where the straight open-ended tubes cannot be used I prefer a curved unguiform-tipped tube eight inches or more in length. This sort of a tube is needed in those extreme cases of prostatic enlargement which elevation of the pelvis will not overcome. Whether in children or adults, the fingers gently used in the rectum will enable one to locate the tube orifice, if necessary, with the utmost precision. Much to my surprise, at first, I found experimentally that a straight unguiform tipped tube acts really like a curved tube by drawing the fluid, not in the direction of its own long axis, but at an angle as indicated by the arrow in the figure. This must naturally be the case, since, as the tube is constructed, the orifice is really a hole in its side. This may be readily demonstrated by holding the tube orifice near the surface of water in a flask, and observing the angle taken by the vortex made by the aspiration. No matter if the tip be buried in the bladder floor then, the current tends to draw over fragments settled at the bottom, and not to draw them directly toward its orifice. This, in the last and critical portion of the aspiration where the fragments are diminished in number, is very important. If the bladder-wall is forcibly aspirated, it will be cut as easily by the sharp sides of the unguiform-tipped tube as by my oblique orifice, the edges of which are rounded. But, as will be stated further on, this is an accident which should be avoided. I am now having my tubes made of aluminium, and also stone-sounds of that metal.

In considering the method of procedure in litholapaxy

FIG. 2.—Frozen Section Made Through a Split Metallic Sound in Full-sized Adult, to Show Surgical Distance to Bladder.

to-day, there are, I think, many facts, deduced from the experience of various operators, which should be well borne in mind. In the first place this, like all other operations in the present time, must be made as much as possible an aseptic one; and although a preliminary treatment, as suggested in the "Vorbehandlung" recommended by some German authorities, is not needed, except in case

of stricture or urine with very unfavorable reaction, etc., yet at the time of the operation the bacteria should be reduced to a minimum. This is best accomplished by first scrubbing and washing the field of operation, and protecting it with antiseptic towels. Instruments should be taken apart, boiled in water where possible, or left for twenty minutes at least in five per cent. carbolic acid solution. For the disinfection of the bladder perhaps the most efficacious and practicable method is that of the greatest possible dilution of the bacteria, if not their complete removal, by thorough washing with the evacuator, using a two per cent. to five per cent. boracic acid, or a 1 to 5,000 or 10,000 corrosive sublimate solution. This should be done as a preliminary to all other steps in the operation, and the evacuator again disinfected. One very important point in the operation, both during crushing and evacuation, and one that is neglected by some operators in this country, although always advocated by such authorities as Ultzmann, Guyon, Thompson, Dittle, and others, is the elevation of the pelvis in adult males. This should be done, not as an exceptional expedient in the operation, but as the rule, by a pillow or specially made cushion placed beneath the buttocks. The prostate is thus usually eliminated from the field of operation, and fragments are more easily crushed and evacuated. The work with the lithotrite, in the average case, seems to be best done by holding the convexity of its female blade against the gently depressed wall of the bladder and steadily crushing fragments, as they are shaken into place by the ordinary slight movements of the instrument, and not by needless "fishing" about. The average stone is thus rapidly crushed and the operation uneventful, although of course any unusual formation of prostate or bladder may make every sort of tactics necessary in order to perform the operation.

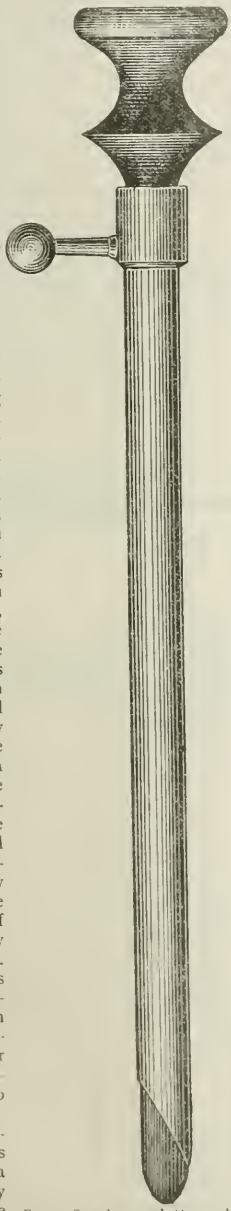

Fig. 3.—Straight, 18 inch, Open-ended Tube, with Stuff for Introduction. Slightly enlarged.

The operation of lithola-paxy should be a bloodless one. There is, I think, a strong tendency among many American operators to force the passage of unnecessarily large instruments. Only such should be used as pass with perfect freedom through the urethral canal, and thus admit of the greatest delicacy of manipulation, and assure the least disturbance of the parts. Instruments in the adult, therefore, varying in measurement from 25 to 30 F., and in children from 14 to 20 F., are the best. Comminution for passage through tubes of any of these sizes is readily enough accomplished. In the early use of large tubes it was naturally interesting to see of what size fragments could be delivered, but it is better for the welfare of the operation to limit them to the size of tubes as above indicated. By doing this we are not losing sight of the great advantage which Professor Otis' demonstration of urethral measurement has been to this operation, but taking intelligent advantage of it. Where the meatus requires division this may be done with the cautery, to avoid an open bleeding wound. Ultzmann has devised a special apparatus for this purpose.

In determining the quantity of fluid to be used for distention of the bladder, it is well to remember that as little as 150 c.c. have been known to cause rupture, and it is well to measure its capacity at first by careful injection. The bladder should always be distended, especially in evacuation, sufficiently to avoid aspiration or pinching of its wall. This sort of injury is the most common cause of hemorrhage, and can be well understood when one examines the delicate vascular wall of the bladder with the cystoscope. Very serious hemorrhage has thus been caused by injury to the venous plexus about the vesical neck, and Antal reports such a case examined by him afterward with the cystoscope. The injury was supposed to have been done with the lithotrite. I have often seen small clotted aggregations over points from which hemorrhage had come in bladders prone to bleed on cystoscopic examination.

Evacuation.—As far as the aspiration of fragments is concerned, I believe that here, as in crushing, the work is done at best advantage when the tube is placed with the orifice at the lowest depressable point of the bladder-wall. Here in time the current is sure to bring every fragment, and such as arrive during the lifting power of the bulb—that is, while there is still current enough to carry them to the inner end of the tube—are sure to be delivered into the receiver. The importance of the shortest possible canal is thus readily seen. If we take experimentally a glass tube four feet in length, we will find that with the expansion of the bulb the sand fragments will be drawn well up toward the top of the tube, but none of them will be carried over. If now we reduce the tube to one-half this length, we find that the fragments are thrown into the receiver in large quantities, and that those that fail to reach the inner orifice stop moving the instant the expansion of the bulb is completed, begin to fall backward, and are then driven out of the tube by the compression of the bulb. If the tube be now progressively shortened, we notice that the evacuating capacity of the apparatus is rapidly increased. The corollary is thus established that, as the length of the tube is diminished the working capacity of the evacuator is increased. The importance of using tubes of such calibre that, with free movement through the urethra the tactile sense is made most delicate, is very apparent.

Many may not realize how slight the lifting power of the ordinary bulb current is. According to the experiments of Desnos [1] it is capable of reaching still fragments at a distance of six to seven millimetres, while those set in motion by the bulb-current may be drawn in at a distance of from twelve to fifteen millimetres. The great advantage of increasing this power is readily seen. With a weak current we are apt to feel obliged at times to place the tube orifice too near the bladder-wall, and thus run the danger of wounding it. The shorter the tube, the longer the bulb expansion continues to draw fragments out of the bladder. To those who have not had much experience with this operation, or have made but little experimental study of it, the difficulty of evacuation and the amount of time it takes may be little realized. Professor Bigelow, in his original article on the subject, said: "Evacuation of fragments is quite an entertaining art, requiring as much skill to accomplish the result in the short-

[1] Antal: Pathologie und Therapie der Harnröhre und Harnblase.

est time as crushing them. Dexterity in the process will hardly be acquired without practice outside the bladder."

I cannot omit mentioning the great advantage which American operators have over those who do not use ether anæsthesia in this as well as other operations. I can

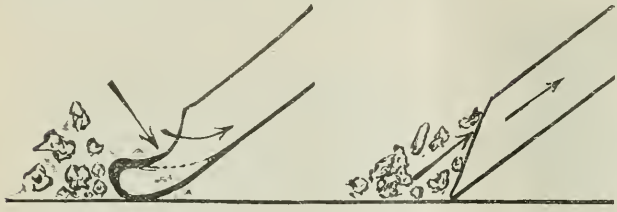

Fig. 4.

speak for the Massachusetts General Hospital at least, and for other clinics in this country as well, I think, and do not hesitate to say that we almost never have a case—and among thousands I have never seen one, even in those with heart lesions—where we have feared in the slightest degree to produce complete anæsthesia. In fact we have never had in our hospital, where ether was first introduced, a death directly attributable to it. This is in strong contrast with those cases where, as I have seen abroad, distention of the bladder has been abandoned because the muscular contractions could not be overcome, and there was fear of forcing the chloroform narcosis. Or, as shown in the following quotation from Antal, "Contra-indications: (*a*) such extreme sensibility of the bladder as cannot be sufficiently reduced by narcosis to admit of the performance of litholapaxy." Likewise, on page 15 of Mosetig-Moorhof's "Surgical Technique," in the chapter on anæsthesia, "As has before been mentioned, narcosis by means of sulphuric ether has now become wholly obsolete." Or from Ultzman, "Krankheiten der Harnblase," 1890, page 250: "In litholapaxy ether anæsthesia is generally insufficient." Sir Henry Thompson prefers ether for this operation.

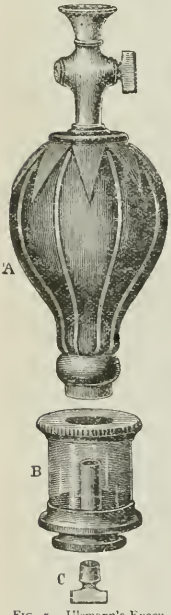

Fig. 5.—Ulzmann's Evacuator. ½ actual size. Very light, but practically like Clover's Evacuator. Length of evacuating canal, about 14 inches.

Cystoscopy.—For the diagnosis and general inspection of a case with stone in the bladder, the cystoscope is often of great value. I have in mind one remarkable case—that of a woman examined by me for Dr. John Homans—where most careful sounding had failed to reveal any stone; and yet with the cystoscope two small phosphatic calculi were easily seen, in the clear distention fluid, lying at the bottom of the bladder. Dr. Homans subsequently removed them by litholapaxy. Two other cases in men I have examined, where a small stone had not been detected by the sound. Both stones were removed by litholapaxy, one by Dr. C. B. Porter at the Massachusetts General Hospital, the other by myself in private practice. Any peculiar conformation of stone or bladder may be readily detected with the cystoscope.

Litholapaxy in Children.—The first American litholapaxy in a very young child was performed by Dr. H. H. A. Beach, at the Massachusetts General Hospital, on May 27, 1889. Dr. Beach was kind enough at that time to use my first model of evacuator, similar in principle to the present, and straight open-ended tubes. In fact, it is in great part owing to his never-failing kindness and co-operation that I have been enabled to accomplish what little I may have for this operation. A No. 17 F. Bigelow lithotrite, kindly loaned by Dr. Mixter from the Carney Hospital, was used for the crushing. The fragments of this stone were shown at the annual meeting of the Massachusetts Medical Society, in June, 1889.[1]

The operation was in detail as follows:

E. S——, aged three years and eight months. Stone in the bladder. May 27, 1889, operation by Dr. Beach. Ether, three and one-half ounces. Boracic solution injected into the bladder. No. 17 F. Bigelow lithotrite easily introduced. Stone grasped apparently the size of a hazel-nut and easily crushed, although quite hard. Fragments removed with Dr. Newell's modification of Dr. Bigelow's evacuator, and short straight open-ended tube six inches in length. With lithotrite then crushed a few small fragments which were readily aspirated. Absolutely no hemorrhage. Calculus stratified phosphatic with hard nucleus, weight twelve and one-half

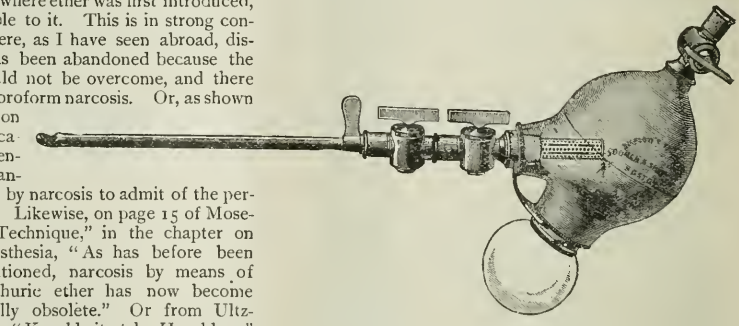

Fig. 6.—Bigelow's Evacuator. ½ actual size. Weight, 24 ounces. Holds 10¾ ounces. Length of evacuating canal, 15¾ inches.

grains. May 31st, has done perfectly well, complains somewhat of pain on micturition. No œdema of glans. No blood. Has not passed any fragments. Slight diarrhœa. June 6th, up and about. June 12th, discharged.

The second operation of this kind in America, as far as I am aware, was performed by me on December 14, 1890, in a boy two years and eleven months of age. The stone was, I believe, the largest ever removed from a child of this age by litholapaxy. Its fragments weighed when dried sixty grains, and were phosphatic in character with dark admixture. My present model of evacuator was used, with a straight open-ended tube five inches in length. A shorter tube could have been readily used, and I shall hereafter have tubes made from four inches and upward in length. The total length of the evacuating canal was seven inches. The operation in detail was as follows:

Case I.—M. R——, two years and eleven months of age. Stone in the bladder. December 14, 1890, litholapaxy with kind assistance of hospital externes Drs. Pease and Lothrop. Ether. Surrounding parts washed with 1 to 1,000 corrosive sublimate solution. The meatus admitted only about a No. 12 F. sound and was divided, after which a No. 17 F. readily entered the remainder of the urethra. Bladder washed with boracic solution, five per cent. Evacuator again disinfected. A No. 5 E. lithotrite, wholly fenestrated, made by Krohne & Sesemann, presented to me by my friend and colleague, Dr. John Homans 2d, was used and worked to perfection. I could readily have introduced a No. 17 F. Bigelow lithotrite which I had with me, but naturally preferred

[1] Boston Medical and Surgical Journal, vol. cxx., No. 25, p. 609.

the smaller instrument, as the stone was not very hard. The largest diameter of the stone seized in the lithotrite was about five-eighths of an inch. If it had not been for one fragment too large to pass through the 17 F. tube, there would have been but one crushing. As it was, I had to introduce the lithotrite a second time. The first fragment seized then, however, was the only one large enough to need crushing, and the operation with a second evacuation was rapidly accomplished. It lasted about fifty minutes, the crushings taking about fifteen and five minutes, respectively, the evacuation and other manœuvres the remainder of the time. The subsequent history of the case was, considerable pain with micturition for the first three days, but no fever and no bloody urine. The penis was somewhat swollen during this time. After the fourth day the patient remained comfortable and played about the room. Twenty-two days after the operation the boy was entirely well, and had gained five pounds.

There is no longer any doubt of the great value and superiority of this operation for the removal of stone from children. Established by Keegan and his coadjutors with the remarkable list of one hundred and fourteen cases, it has been sustained by many valuable supplementary lists. Among those next in value probably stands that of Freyer, thirty-four cases, among which I believe was the youngest child thus far operated upon. This patient was a child of eighteen months, from whom a No. 5 E. lithotrite and a No. 6 E. cannula removed, in eight minutes, a stone the dried fragments of which weighed three grains. Dr. D. P. Allen, of Cleveland, reported before the American Medical Association, in June, 1889, four admirable and successful cases. They were, however, patients already in their teens. I have performed litholapaxy successfully in a boy of eighteen years.

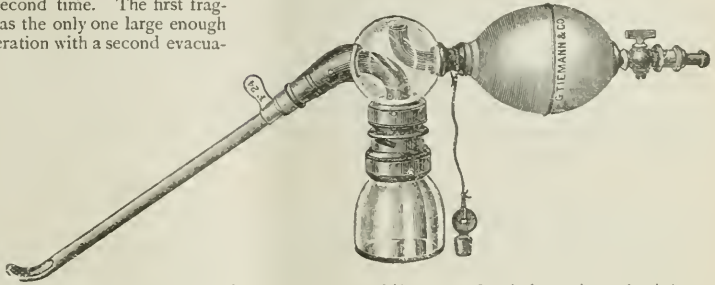

Fig. 8.—Otis's Evacuator. ¼ actual size. Weighs 10 ounces. Holds 8 ounces. Length of evacuating canal, 14 inches.

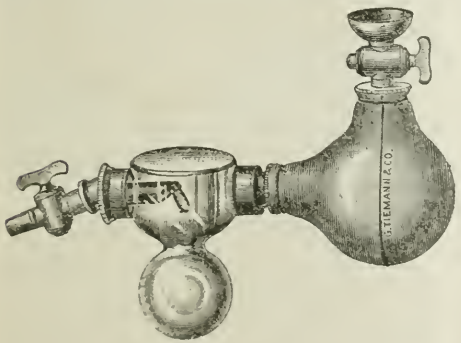

Fig. —Thompson's Evacuator. ¼ actual size. Weight, 27½ ounces. Holds 12½ ounces. Length of evacuating canal, probably 14 inches.

As far as this operation in very young children is concerned, I believe, so admirable are its results, that where there are no contra-indications it is better to let the stone remain until the child is of an age to have it removed by litholapaxy. This, by keeping the urine dilute and the child well nourished and moderately quiet, can be readily done. My patient's condition was much improved by adopting this plan for three months preceding the operation. This I did, not on account of the urethral calibre, but with regard to the poor physical condition. The child improved greatly during these three months, and was in fine condition at the time of the operation. By following this plan we should avoid the mutilation of lithotomy, which, with its various sequelæ, stricture, prostatic obstruction, residual urine, cystitis, etc., may, as was said by some old French authority, I believe, be the death-mark of him who receives it. How often we see children who with no great discomfort have carried stone, as far as symptoms could indicate, for years!

The tabulated cases, as far as I have been able to find them in the "Index Medicus" and elsewhere, are as follows:

Litholapaxy in Children.

Operator.	Number of cases.	Recovered.	Died.	Country.
Keegan	114	110	..	India.
Freyer	34	34	..	"
Marshall	5	5	..	England.
Beach	1	1	..	America.
Newell	1	1	..	"

It was my good fortune to be the recipient of a double term as house officer at the Massachusetts General Hospital under Professor Bigelow's direction, which gave me, instead of the customary single service, an opportunity during two years to work with him soon after the publication of his earliest papers upon the new operation. I remember well his great enthusiasm upon the subject, and his unbounded devotion to his patients. One could not work with him continuously without being impressed with the importance of developing every mechanical possibility that would reduce difficulties and make his great discovery practicable for all. No one urged this point more than he in the critical remarks with which he accompanied his operations. A few months before his death I called to show him my proposed changes in evacuators, feeling sure of his kind interest in any instrumental improvement that was likely to facilitate his operation. He expressed much interest in my new model, which I was to exhibit before the Suffolk District Surgical Section of our State Medical Society, and asked me to state there for him that

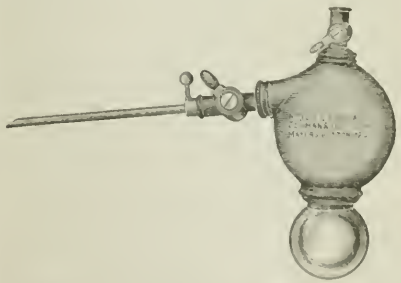

Fig. 9.—Newell's Evacuator.* ¼ actual size. Weighs 9¾ ounces; holds 9¾ ounces; length of evacuating canal, as used in children and adults, 6 to 10 inches. Special advantages may be considered to be, 1, its simplicity, being without trap and with shortest evacuating canal thus far made possible; 2, its lightness; 3, taper joints to admit of readily turning the tube orifice in any direction without uncoupling; 4, form of stop-cock, which may be readily operated with a single finger; 5, aluminium tubes; 6, non-corrodable, being made of rubber and glass.

he had hoped to overcome the problem of weight in the future by the use of aluminium fittings, promising if able to attend the meeting. At the close of a most delightful interview he said, "Well, Newell, I've no doubt that you have got a good evacuator, and after all, a thing is bound in the end to stand on its merits." This had certainly been shown but a short time before in his case, by the most courteous acknowledgment of his litholapaxy published in the London *Lancet* by Sir Henry Thompson.

In conclusion, if I have contributed anything to make Dr. Bigelow's operation easier of execution and more practicable for the general operator, it is the tribute that I desire to pay the genius that illuminated the surgery of America for forty years.

THE TREATMENT OF MENORRHAGIA AND METRORRHAGIA BY THE CHEMICAL GALVANO-CAUSTIC ACTION OF THE POSITIVE POLE.[1]

By AUGUSTIN H. GOELET, M.D.,
NEW YORK.

ALTHOUGH these conditions, when present, are to be regarded as a symptom rather than a disease *per se* they are usually of sufficient importance to require separate consideration, and a plan of treatment directed to their control independent of the cause. Fortunately, however, the galvanic treatment instituted for the relief of this symptom is generally peculiarly suitable also for the disease or condition which produces it. Hence, in attacking the endometrium for the control of the hemorrhage, the causative condition is, likewise, not only indirectly, but directly benefited also.

In adopting any line of treatment much depends upon the associated condition as to how active it may be, and this applies especially to the use of galvanism, for the strength of current which it is safe to use depends much upon the pathological state of the uterus and the surrounding tissues. Thus, when associated with a chronic peri-uterine inflammation or exudation, we must proceed cautiously and feel the way to the higher currents which are sometimes necessary to control the bleeding, never using more than 30 to 50 milliampères at the commencement or until the inflammatory condition has been subdued.

There are some minor but important details in connection with the treatment of these conditions which must be borne in mind. If the hemorrhage be apparently aggravated instead of being checked, as expected, by the applications, the cause of the failure is to be sought before the method of treatment is condemned and abandoned. It will usually be found to be due to the crudeness of the manipulations. Bear in mind that there exists great engorgement of the endometrium, and that even the introduction of the sound, ever so carefully done, will generally intensify the flow. An abrasion may have been produced in introducing the electrode, which continues to bleed after its withdrawal because the electrode did not happen to remain in contact with it during the application. Perseverance, with an appropriate electrode, will undoubtedly yield success. Perhaps the electrode has not been kept still during the application, but either carelessly or intentionally it has been moved about in the cavity, which will not only irritate but will actually defeat the object of the application—cauterization—by preventing constant and sufficient contact of the electrode with the bleeding surface. Perhaps the strength of the current is not sufficient, and the patient will not submit to the pain produced by a current of suitable strength, or to the proper duration of the application. In this case an anæsthetic must be given, but it will not be necessary to produce deep anæsthesia. A small quantity of chloroform or æther on a cloth, administered after the same plan as in childbirth, will be sufficient to divert the patient's mind from the application, and the first exhilarating or intoxicating effect affords sufficient indifference to pain. The electrode is to be placed in position and the current turned on very gradually as soon as the cloth is placed to the patient's nose, and she is told to breathe deeply as in taking gas, and as the pain increases she is to breathe more deeply and more rapidly, and she will not feel the pain. Continue talking to her and insist upon the necessity for deep respiration and she will tell you afterward, perhaps, that she felt the pain slightly, or knew what was being done, but did not mind it.

I have found this method of producing quick and partial anæsthesia or indifference to pain very convenient in office work, because consciousness is almost immediately restored as soon as the anæsthetic is withdrawn, which should be done when the current is turned off. But the patient must remain quiet for a short time without being disturbed from the couch upon which the application has been made until the immediate effect of the application has passed off. It will, of course, be necessary to have the assistance of a competent nurse who has been trained to assist in such cases, or else the patient may prove troublesome to manage.

Such applications as require anæsthesia are not, of course, to be done at the office as a general thing, for the patient should in some cases remain in bed until the reaction from the treatment has subsided, and she would be more comfortable at home and it would be safer; but if you know your case it may be treated thus at the office with perfect safety, and certainly with greater convenience to the operator.

For controlling uterine hemorrhage the peculiar hæmostatic action of the positive pole is taken advantage of, and to produce a permanent result a decided caustic action must be obtained. There are two methods of application; viz., either with the platinum sound to the whole length of the canal, from external os to fundus, or by sectional cauterization, the latter being more effective.

The electrode must fit the cavity snugly when sectional cauterization is to be done, and if the cervical canal is too small to admit a size sufficient for this purpose, it must be previously dilated with a steel dilator. It will not be necessary to employ much force to accomplish this, and extreme care should be observed that no injury is produced. The uterine cavity only is to be submitted to this sectional cauterization and the cervical canal is to be avoided unless there is some special indication, because it is more sensitive than the cavity of the uterus and unnecessary pain is to be avoided. Besides, contraction of the canal could easily be produced by a strong positive galvanic cauterization after dilatation and the escape of the thick plug of tenacious mucus which protects the canal from the effect of the positive pole when it is present.

We are to expect a better and more prompt effect from a cauterization after dilatation, not only because of the better contact of the electrode with the cavity, but also because the dilatation allows the secretions to escape from the cavity and the electrode comes more closely into relation with the lining membrane than when it is protected by a coating of the secretions.

It may readily be seen that a thorough familiarity with the details of the application is necessary to insure success, and it would be unreasonable to expect it in the absence of a perfect understanding of the requirements of each individual case.

If the case be one where the bleeding is not excessive and the uterine canal is small throughout its entire length, a few positive galvanic applications with the platinum sound exposed from the external os to the fundus, and with a current of from 50 to 100 milliampères used for five minutes every second day, will suffice to control it; because in this instance, the electrode, although of small

[1] Read before the New York Academy of Medicine, Section on Gynecology and Obstetrics, January 22, 1891.

calibre, comes sufficiently in contact with the walls of the cavity to produce effective cauterization. Even in some instances where the bleeding is excessive, if the canal is narrow, this method of application will be effective, though it may sometimes be necessary to increase the strength of the current to 150 milliampères. The treatment is not to be discontinued as soon as the bleeding is checked, but should be repeated once or twice a week, using a milder dose, and the case should be kept under observation until it is certain that a cure has been effected. And any existing cause constituting the primary disorder must receive appropriate treatment also. An antiseptic douche of creolin solution should precede and follow each application.

Whenever the bleeding is excessive or the uterine cavity is large, it will be necessary to resort to sectional cauterization, which is at once more thorough and effective than the other method. It is done in this manner, viz.: Selecting an electrode suitable for the positive pole (carbon or the prepared steel) of such a size as will fit the cavity snugly and about three-fourths of an inch in length, it is passed up to the fundus along the finger as a guide, the patient being in the dorsal position, and a large clay electrode on the abdomen, the current is turned on and increased gradually until 100 or 150 milliampères is reached at the first sitting if possible and the case is urgent. (And if the uterus is insensitive, as is often the case in fibroids, the dose may be pushed still farther if it is required.) The electrode is held firmly against the fundus by the operator for from three to five minutes. Then, without turning down the current, it is withdrawn the length of the exposed surface, as represented by the distance between the notches on the insulated shaft of the instrument and can be felt by the finger in the vagina against the cervix, which brings the acting surface of the electrode in contact with a fresh portion of the cavity. Severe pain will sometimes be produced by this change of position, but it is only momentary and will usually subside without altering the strength of the current. If it should not, however, the current may be turned down to a bearable point and again increased. This manœuvre is repeated until the whole surface is gone over and the internal os is reached, when the current is turned off slowly and the electrode removed. If thoroughly done, this application need not be repeated for a week, and unless it is necessary to prevent intercourse a tampon is not used, but the vagina is douched with an antiseptic solution. The tampon, if used, should consist of a long, narrow strip of creolin or iodoform gauze placed loosely in the vagina and allowed to project a little outside the vulva, and should be removed within twenty-four or thirty-six hours.

If the subsequent behavior of the case demands it, this cauterization may be repeated every three days until the bleeding is stopped. It is advisable to continue weekly applications with the platinum sound until one or two normal menstruations have passed to make sure the result, unless the causative condition demands other treatment which would interfere. When the action of the negative pole is called for in treating the primary disease after the hemorrhage is controlled, it can generally be used without risk of provoking its return.

The rules laid down above will apply to this symptom occurring in connection with all conditions which give rise to it, but when there is a fungus endometritis, the result will be more promptly obtained if a thorough curetting of the cavity precedes the chemical galvano-cauterization. A mild cauterization of from 60 to 100 milliampères, may immediately follow this operation, or it may be delayed until the effect of the operation has passed off. Oftentimes, however, positive cauterization will prove effective when one or more curettings alone have proved unavailing. And where this operation is contraindicated the cauterization may be depended upon to do its work effectively.

When hemorrhage follows abortion, the curette should always be used first to remove all retained debris, and positive cauterization may be permissible subsequently if the hemorrhage is persistent.

When it is due to the pressure in the uterus of polypi or submucous fibroids it is not good treatment to use galvanism until they are removed. Then thorough cauterization of the endometrium will prevent a return.

In submucous fibroids where their removal is not possible, galvano-chemical cauterization (positive) will prove beneficial and effective in controlling hemorrhage.

A great advantage in favor of this treatment is that it does not necessitate confinement to bed, and it can generally be carried out at the office. If, however, the bleeding or the condition is such as to compel the recumbent posture, the treatment must be given at the bed-side, but it will entail a very much shorter period of rest than any other treatment.

The chemical galvano-cauterization has been suggested for the control of the hemorrhage due to uterine cancer, and also for the destruction of the diseased tissues, but the galvano-caustic wire is so much quicker and more effective, that I see no reason for its advocacy. The very strong currents necessary to produce a reliable effect (and a very much higher power than is generally used is needed) would prove a barrier to its use, unless some means is discovered for administering it in such doses with safety.

I will relate briefly the histories of two cases where this method of treatment was successful after the curette had failed, and I have selected these from among many because they were the most obstinate I have had to deal with.

Case I.—Miss S——, aged forty-two, puberty at fourteen; menstruation regular and normal until six years ago when she began to have menorrhagia and a burning pain in the left side of the pelvis.

Dr. Banks, of Englewood, who sent her to me, curetted the uterus freely with only temporary benefit. She was only a little better for two months. At the time he sent her to me for treatment, October, 1889, the uterus was enlarged, measured three and a half inches, was sensitive and not freely movable, there being a contraction of the left broad ligament, drawing it to that side, and there was metritis and endometritis. She was losing blood constantly, never stopping for more than two days at a time.

She received thirty-six positive galvano caustic applications to the uterine cavity, varying in strength from 50 to 150 milliampères. Only three of these were sectional cauterizations. The treatment extended over a period from October to June. She began to menstruate regularly in December, and it was twenty-eight or thirty days since the last period and the duration was three days. From that time until June the interval was twenty eight days, and the duration of the period two to three days.

June 30th, when the thirty-sixth application was made, I find this note in my case-book: "Uterus is the size of the virgin organ, measures two and a half inches, is movable and not sensitive, no ovarian pain."

She has been kept under observation since then by my friend, Dr. Banks, who assures me she is still menstruating normally, and has had no return of the pain of the left side. The whole treatment was carried out at the office.

Case II.—Mrs. V——, aged twenty-four, married three years. She was regular from puberty, though rather free until her marriage, when menstruation began to appear every two weeks and was prolonged for nine or ten days.

After consulting several physicians, who treated her by medicines, and not locally, she, by the advice of some friends, consulted a prominent gynecologist of this city and entered his sanitarium for the purpose of an operation.

In November, 1889, she was put under an anæsthetic. The cervix was dilated with such force as to split it, but this was promptly sewed up. The cavity was then very thoroughly curetted, we must believe with a sharp curette, for he is one very prone to use this instrument. She left

the sanitarium December 10th, and the first menstruation after the operation began December 25th, lasting for a week. In January her menstruation appeared the 19th, and continued as a bloody discharge until the 28th, when it commenced freely and lasting until February 16th, it made its appearance again February 20th, and continued as a hemorrhage until the 28th. After that date it continued as a bloody discharge until the time she consulted me, March 10th. She discontinued her attendance because he proposed another operation.

On examination I found a slightly enlarged sensitive uterus, normal in position, but fixed. To the right, and somewhat posterior to the uterus, could be felt a slightly enlarged, very sensitive, prolapsed ovary. I commenced treatment with the platinum electrode to the whole length of the canal and 50 milliampères, of five minutes' duration, three times a week. This was soon increased to 100 milliampères, but at no time did it exceed that figure. The duration of the treatment was from March 10, 1890, until about August 1st. I succeeded in checking the slight flow at once, and her regular menstruation appeared on the 19th and lasted until the 24th. During the remainder of the treatment her menstruation never appeared under twenty-eight days, and frequently went a week over the time, and its duration was never more than from three to five days. She had forty positive galvano-caustic applications to the canal during that time, and out of this number I gave only two sectional cauterizations of 50 milliampères. During the course of the treatment she received two positive galvano-punctures into the sensitive ovary of 30 milliampères each, and of five minutes' duration. She has been kept under observation since August, and has had an occasional application merely to make sure the result, but for the past month she has had no treatment, and her last menstruation was normal. The uterus is somewhat more movable than it was before, and the ovary, while it still remains where it was, is scarcely sensitive. She can attend to her usual household duties, walk, and ride without the inconvenience which she experienced before, and considers herself entirely well.

I am tempted to, and will, relate another case which will show how hemorrhage from the uterus with a fibroid can sometimes be very promptly arrested.

I was asked by Dr. F. H. Markoe, one day last July, to see a case of his in St. Luke's Hospital and to treat her there, because he wished to see what value there was in electricity for controlling hemorrhage. It was a case of bleeding fibroid, and she had been losing blood for a long time. The flow, which was at first intermittent, had now become constant, and she was blanched from loss of blood. I commenced with a platinum sound in the canal to give her positive galvano-caustic applications of 50 milliampères, five minutes each time. This in the midst of the hemorrhage. The applications were repeated twice a week. In less than ten days the hemorrhage ceased entirely. Afterward the strength was increased to 100 milliampères. The reason for this rapid action upon the uterine canal with a platinum sound was because the canal was very small and tortuous, and the electrode passed the full length of the canal, four and a half inches, and fitted it so as to produce effective cauterization on all sides.

She remained some time in the hospital, perhaps two months, during which time she received treatment for the fibroid. Not even normal menstruation reappeared. I gave her several applications of the negative pole during the time without causing any reappearance of the hemorrhage. After she left the hospital I kept her under observation, and up to this date—and I see her weekly—there has been no return whatever of the flow, nor even of menstruation, and I have, since she left the hospital, repeatedly used 150 milliampères negative to the canal for five minutes at a time. She is improving, and the tumor is reducing in size.

This last case shows that in those cases of bleeding fibroids the hemorrhage can be positively controlled by the positive pole used properly. It also leads us to suppose that possibly we may arrest menstruation completely in some cases, if not in all, and thus bring about an artificial menopause, which is considered a desideratum in all fibroids.

351 West Fifty-seventh Street.

REPORT OF THREE CASES OF NEPHRECTOMY.

By F. KAMMERER, M.D.,

SURGEON TO THE GERMAN AND ST. FRANCIS HOSPITALS, NEW YORK.

I HAVE ventured to present to the Section on Surgery the following cases of nephrectomy as possessing a few points of special interest.

CASE I.—T. R——, aged twenty-nine; married at eighteen; has had two miscarriages. No history of tuberculosis or syphilis. Has been ailing since her last miscarriage, three years ago, and her sufferings (pelvic pain, irregularity in the functions of rectum and bladder) have gradually increased so that she is unable to do any work. On admission to the hospital the patient's general condition was very low; the abdomen was very sensitive to pressure, especially in the right iliac region. Under anæsthesia a fluctuating tumor the size of an orange was made out to the right of the uterus, firmly imbedded in adhesions; the ovary on this side was not detected. The left ovary and tube were similarly affected but in a less marked degree. I diagnosed double pyosalpinx, with pelvic peritonitis. As the condition of the patient demanded operative interference the ovaries and tubes were removed on August 6, 1890. The operation was very tedious and difficult, owing to the adhesions and infiltration. The lower part of the small intestine was firmly attached to the mass representing the right ovary and tube, and had to be cut away. Many ligatures were necessary before the mass could be removed. The removal of the left appendages was more easily accomplished. The abdominal incision was closed with the exception of its lower angle, from which an iodoform gauze tampon, packed into the pelvis, protruded. At the end of forty-eight hours this was removed and the abdomen closed. During the first few days there was a considerable rise of temperature, but this quickly subsided, and the patient seemed to recover slowly. On August 18th the abdominal sutures were removed. On the 23d the patient, who had been feeling uneasy for several days, began to develop symptoms of ileus. Temperature, 103.6° F. The abdomen was distended and tympanitic, excepting the right lumbar region, where dulness on percussion, extending to the lower angle of the abdominal incision and somewhat to the left, was noted. I concluded that a loop of intestine had become adherent at this point, and therefore decided on re-opening the abdomen, more so as vomiting, distinctly fecal in character, had set in. Careful dissection at the lower angle of the cicatrix showed that no intestine was adherent at this point but that the area of dulness corresponded to a part of the peritoneal cavity, shut off by adhesions, from which a large quantity of sero-purulent fluid escaped with a distinctly urinous odor. In the further course of the case an abdominal urinary fistula persisted When the bladder was injected with fluid a steady stream would, at the beginning of this procedure, flow from the fistula, but this ceased when the viscus was fully distended, proving that the fistula was of the ureter and not of the bladder. An examination with the cystoscope dispelled any doubt as to which ureter was affected. From the left urethral orifice, urine was seen to flow into the bladder at intervals of from two to three minutes, and in a continuous stream when pressure was exerted on the kidney. No urine came from the right ureter, either spontaneously or upon pressure on the corresponding kidney. The quantity of urine passed by the urethra was

about twenty-five ounces in twenty-four hours, of normal quality, evidently secreted by the left kidney only.

On September 7th the patient was taken with a chill and subsequently had high temperatures. Puncture in the lumbar region demonstrated the existence of a large perinephritic abscess. Assuming that the existing condition would prove a constant source of danger to the patient, I decided to remove the right kidney. The lumbar incision was practised, and the abscess at the lower pole of the kidney first incised and thoroughly disinfected. Only at this point did the enucleation of the kidney present any difficulties. A small rent in the peritoneum was immediately closed with a running catgut suture, giving rise to no further trouble. After ligation of the pedicle en masse, the wound cavity was plugged with iodoform gauze. Recovery was uneventful. The removed kidney was entirely healthy; within two weeks the remaining kidney secreted about fifty ounces of urine in twenty-four hours. During this time traces of albumin were frequently found, but no blood or casts.

Case II.—K. D——, aged twenty-eight, gives a family history of tuberculosis. Six years ago she had an attack of pleurisy; two years ago suppuration of cervical glands. About a year ago pain set in in the left lumbar region and the back, and the urine became gradually turbid. When she first consulted me last summer, she was very much emaciated. At the site of the left kidney a tumor was felt about twice the size of a normal kidney and somewhat tender on pressure. The urine contained pus, but no tubercle bacilli. As aspiration demonstrated the presence of pus, I exposed the organ by the lumbar method, and made a free incision into the cortex of the kidney. The condition of the patient was too critical for nephrectomy. During the succeeding four months the wound gradually closed, but a renal fistula remained, secreting much pus and urine. An examination with the cystoscope revealed the fact that no fluid entered the bladder from the left ureter, but pus when firm pressure was exerted upon the corresponding kidney. Apparently clear urine emptied into the bladder from the right ureter. Of late there had been a rise of temperature in the evening from 101° to 103° F., and a reformation of the tumor corresponding to the left kidney. The patient's condition being good, I now decided to remove the kidney. There was no great difficulty in isolating it from the surrounding structures. When the pedicle was exposed, it was found that the ureter and pelvis were thoroughly implicated in the disease. I placed a strong silk ligature around the pedicle and cut away the kidney, leaving quite some of the degenerated substance on the distal side of the ligature. During further manipulations, however, this tissue broke down and the ligature slipped. This was fortunately detected before any serious hemorrhage occurred. The pedicle was caught with four artery forceps, which were included in the dressing and removed on the fifth day, no further mishap occurring. The wound is almost entirely closed to-day, but the urine still contains some pus.

Case III.—B. P——, a married lady, aged thirty-four. Eight years ago, after childbirth, she was first taken with pain in the left side. Four years ago she was treated in Denver, Col., for some kidney trouble, causing œdema of the entire body that persisted for several months. More especially since this attack she has been suffering from pain in the region of the left kidney, and has experienced a feeling of numbness in the left lower limb. A year ago she first noticed a tumor on the left side, which has been increasing rapidly during the past few months. I saw her about a month ago. Through the lax and thin abdominal walls a tumor was felt to occupy the left lumbar and hypochondriac regions. It was as large as a child's head, and reached fully to the median line. Firm and hard to the touch, it had a slightly uneven surface. It was somewhat movable and was apparently nowhere adherent to the lateral or anterior abdominal walls. It was readily recognized as belonging to the kidney, by inflating the descending colon from the rectum, the colon passing over and somewhat to the outside of the tumor. The urine was acid and contained a small amount of pus. During cystoscopy firm pressure on the tumor caused the escape of distinctly turbid urine from the left ureter. Urine was also seen to escape from the right ureter, but no very satisfactory information regarding its quality and quantity was obtained. The appearance of the growth, its rapid increase in size, its tenderness, and the small quantity of pus in the urine, all in combination with a negative result of an exploratory puncture of the tumor, led me to the diagnosis rather of a growth than of suppurative disease of the kidney. On account of doubts still entertained as to the diagnosis, I decided upon the lumbar in preference to the abdominal incision. I came upon a fibrous capsule, fully an inch thick in some parts; after cutting through it the kidney was found firmly adherent to it. It proved a very difficult matter to peel out the kidney from its capsule, and during the necessary manipulations the tumor burst, and from the rent in the kidney about a pint of turbid urine escaped. Introducing my finger into the opening, I readily detected a stone in the lower part of the pelvis. Finally, the pedicle was reached and severed, the vessels being ligated as they were cut. The A. C. E. mixture was employed as an anæsthetic, the patient's condition being considered too low for the exhibition of chloroform only. The temperature was normal after operation, and her general condition at first gave fair hopes of a speedy recovery. Unfortunately, however, she died on the third day from complete suppression of urine. An autopsy was not permitted, but the other kidney was felt at its normal location through the operating wound, and appeared to me and two gentlemen of the house-staff of the German Hospital of normal size.

Quite a number of cases have been reported, in which nephrectomy has been done for the relief of urinary fistula, generally with favorable result. I was surprised to find only three cases[1] of uretero-abdominal fistula among them, as injury to the ureters during difficult abdominal operations seems to have occasionally occurred. In such cases, when the mishap is discovered at the operation, attempts have been made to transplant the divided end of the ureter to some part of the abdominal walls, or nephrectomy has been resorted to. In Simoni's case it is simply stated that an abdominal fistula developed, but in Le Fort's, the result of a stab-wound, we are informed that the external wound was closed, and that on the fourth day only symptoms of localized peritonitis set in. At the end of another week there was dulness on percussion of the right side of the abdomen. Eighteen days after the trauma distinct fluctuation was felt, and an incision above the inguinal fold gave exit to a large quantity of fluid, and established a uretero abdominal fistula. Nephrectomy unfortunately resulted in death. In this case the ureter must have been cut at the time of the accident, and it is remarkable that only after so long an interval did the accumulation of urine become noticeable within a circumscribed portion of the abdominal cavity. There was no escape of urine by way of the abdominal tampon in our case during the first days succeeding the removal of the appendages. It is therefore safe to assume that the ureter had been included in one of the many ligatures en masse, and divided below it. Later on, when the general peritoneal cavity was shut off by adhesions, the ligature gave way under pressure of the accumulation of urine in the pelvis of the kidney. But then the dangers of peritoneal infection no more existed. Might this experience not be utilized in cases of injury to the ureters during abdominal operations, when the condition of the patient counter indicates immediate nephrectomy. Close the ureter with a ligature or a forceps, temporarily, and introduce a tampon into the

abdominal cavity to the point where the ureter has been divided. Later on, when the patient has rallied and a urinary fistula persists, nephrectomy will prove a simple procedure.

In the case of tubercular kidney which I have reported previously, nephrotomy had a double purpose. Contrary to the experience of Madelung,[1] and in accordance with what has been observed by other surgeons, the patient gained over twenty-five pounds in weight in a few months. Furthermore, I was only enabled after a renal fistula had been established to determine that the right kidney was also slightly affected. Cystoscopy was resorted to before and after nephrotomy. The urine issuing from the right ureter at both times was thought to be clear. I am positively convinced that after nephrotomy no urine passed down the diseased ureter into the bladder. The large quantity coming away by the renal fistula, measurements of the urine from the other kidney extended throughout several days, and especially cystoscopic examination, during which the ureter of the nephrotomized kidney was watched on many occasions as long as the very willing and plucky patient could endure, left no doubts as to the certainty of this observation. Besides only on firm pressure on the kidney did pure pus escape from the ureter into the bladder. This was explained during nephrectomy. The ureter was found converted into a thickened strand as far as it could be felt, evidently occluded by tubercular masses. I do not wish to conclude from this one experience that nephrotomy will always prove successful in establishing complete drainage of the urine from the affected kidney, but, if we can verify this with the cystoscope, then the diagnostic importance of nephrotomy in determining the condition of the other kidney cannot be disputed. While firmly believing in the great value of cystoscopy, especially in diseases of the bladder, I have not myself been so fortunate in the diagnosis of kidney troubles with the cystoscope.

In the last case reported to-day I was not quite sure whether the urine from the right ureter was clear or not. In two other cases of tubercular disease I was not able to get a clear view of the bladder, from the fact that the water injected immediately became turbid. In both these cases I resorted to explorative epicystotomy, with the most gratifying results for myself and the patients. With the aid of an electric lamp introduced into the bladder I was enabled to determine the implication of both kidneys in one instance, and the extended tubercular disease of the bladder and of one kidney in the other. Considering its simplicity as a surgical procedure, its value as a diagnostic aid, the relief to the patient with irritable bladder from infrapubic drainage, epicystotomy as recommended by Schede ought to be more frequently resorted to in these cases. Aside from the more conspicuous lesion of which we become aware with the diagnostic methods already alluded to, there are pathological changes in the kidney which affect its secreting power, of which we gain no knowledge by simple determination of the quantity of urine secreted and by its microscopic examination. A person in apparent perfect health may have serious kidney trouble, which can only be detected by a quantitative analysis of his urine. Tuffier[2] has given surgeons some valuable advice on this point. In an admirable essay he has demonstrated that regeneration of renal substance takes place to almost an unlimited extent, even after removal of one entire kidney and part of the remaining organ, if only a certain amount of perfectly normal renal tissue is left in the body. But if there exists a general disease of both kidneys, no such regeneration takes place, and surgical interference with such organs is followed by most disastrous consequences. I have looked through Newman's[3] statistics of nephrectomies and I believe have found clinical corroboration of Tuffier's experiments. The author has collected fifty-four deaths after lumbar nephrectomy, of which 7 were due to suppression of urine and uræmia. These 7 occurred, 1 in hydronephrosis, 2 in suppurative disease without calculus, 3 in suppurative disease with calculus and 1 in tubercular disease; no deaths from suppression after lumbar nephrectomies for movable kidneys, cystic kidney, traumatic lesions or tumors (his statistics of abdominal nephrectomy do not allow similar conclusions; however, I prefer to place reliance rather on those operations when the element of peritoneal sepsis is entirely out of question. May not some of the deaths from suppression and uræmia after the abdominal method be due rather to such a cause?). In other words, suppression of urine in all those affections liable to attack both kidneys. We all know that following nephrectomy there is a partial suppression, lasting a day or more, in almost every case. This is in all probability of a reflex nature and temporary. But if the remaining kidney does not resume its functions and the patient dies of uræmia I fear we must admit that this organ was also diseased at the time of surgical interference, that our diagnostic resources have failed to decide this point, and that nephrectomy was not a justifiable procedure.

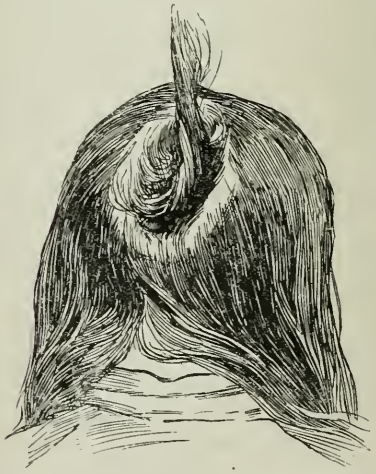
CASE OF TRAUMATIC EPILEPSY.

By J. ELVIN COURTNEY, M.D.,
ASSISTANT PHYSICIAN, STATE HOSPITAL, POUGHKEEPSIE, NEW YORK.

THIS case is reported especially on account of the great injury to the skull in early life and extensive exposure of motor areas of the cortex to slight traumatic influences, and also as illustrating generally some features of epilepsy.

Dora B——, aged four months, fell fifteen feet, striking her head. A large swelling in the occipito-parietal region was found, and there was a state of profound coma for three days. The injury seems to have been an inversion of the angles of the bones forming the posterior



fontanelle. The deformity caused, even after subsidence of the swelling, was so great that the mother devised a cap to hide it. Nothing untoward occurred until the age of two years, when she fell from a swing, striking the back of her head, when she was again comatose for two days, and for several days there was an enlargement at the seat of original injury. The family physician noticed that gentle pressure on this protuberance caused the child to close its eyes as if asleep. At the age of five she was

struck on the head by a playfellow, and for the first time had several severe epileptic convulsions. After this ordinary epileptic seizures occurred at intervals of from six months to two years until puberty, fourteen years But the parents say that no fit occurred without a fall or some accidental hurt to the injured place. and that she guarded it with instinctive care. She was well developed, apt at school, and helpful at home. Fits now occurred one every two or three years, without assignable external cause, and epigastric aura began. She described a "drawing" and "lump" in the left side. So distinct was this that the parents decided there must be a "tumor" there. She could usually foretell the fit long enough to betake herself to bed. Attacks of petit mal were frequent, usually after a hearty meal; she would then sit or lie down for a few minutes. At the age of nineteen, after several severe fits, she had a maniacal outbreak and was sent to the hospital at Poughkeepsie, where she remained eight months, making a good recovery and having only one fit during the time. For the next two years the fits were more frequent, one every three or four months, and attacks of petit mal were very frequent. At the age of twenty-two she was in status epilepticus for two hours. This was followed by partial left paraplegia and a state of such utter confusion that she was readmitted to the hospital. The elongation of the skull was noticeable, especially on the left. It seemed that the separated parietal angles had grown backward instead of in the natural rounded direction. A photograph (page 370) taken then shows the depression with the well-defined margin. The measurements were: antero-posteriorly, 5¼ inches; transversely at the middle, 2½ inches. The scalp fell into the opening ¾ inch below the margin. The bony margin had an inward slant, but it was evident that over a considerable area the brain had no other protection than the scalp and its aponeurosis. The hebetude following the status epilepticus soon passed off and no mental deterioration remained. Her care of the "soft place" was jealous; she would not allow the nurse to touch the hair over it, and always kept her hand on the wrist of any one examining the place. For two months after readmission nothing notable happened. At noon one day she suddenly told the nurse that she had "that feeling" in her side, and hastened to bed. She immediately passed into status epilepticus, convulsions succeeding each other very rapidly, and died of asphyxia, in four hours. During the fits it was noticed that, while the motor storm rapidly involved all the muscles, it began on the left, and the sequence of the involvement of muscles indicated that the discharge began in the injured area. The scalp over the opening, from being flaccid, became bulged and quite tense, becoming less so at the end of each tonic stage, but not entirely subsiding in the short intervals between the fits. The parents had noticed this "swelling" of the scalp over the opening when the fits came on. Permission could only be obtained to examine the opening. In retracting the scalp care had to be used to prevent tearing into the cavity. The covering removed was only the aponeurosis of the scalp. It was opened and showed a free serous surface. The exposed part of the brain lay between the fissure of Rolando and the occipito-parietal fissure of the right hemisphere. About two-thirds of the opening lay to the right of the median line. The bone was thickened and had grown from the inner table, especially at the front and back, so that the antero-posterior measurement was only 2⅜ inches on the inside. Across this space stretched delicate bands, probably the remains of dura mater. The brain was not flush with the inner margin of the opening, there being some atrophy and flattening of the convolutions. The falx cerebri was somewhat deflected to the left. About an ounce of cerebro-spinal fluid was in the cavity. The vessels of the pia were greatly engorged. It is to be remarked in this case, 1. That from this extensive trauma in infancy, no fits occurred until the age of five years, and none without external injury until puberty, and that epigastric aura and petit mal appeared at that period. 2. The indication of cerebral engorgement during the fits, the cerebro-spinal fluid being strongly forced out through the opening during the clonic stage, lightly distending the scalp, and then gradually subsiding. 3. The greater frequency and violence of the seizures, and at last status epilepticus, at the age when hyperplasia of bone about the margin of the opening in the skull and complete ossification, offered unyielding obstruction to further brain expansion.

Progress of Medical Science.

Microbic Groupings.—Drs. Babès and Cornil call attention to the following: 1. Association of closely allied varieties of the same species, as, for example, the varieties of the microbe of pulmonitis and the bacillus of typhoid fever, respectively. 2. The almost constant association of one microbe with another in a given disease, as the streptococcus and the bacillus of diphtheria, the microbe of Schütz, and that of hemorrhagic septicæmia in equine typhoid fever. 3. Association in traumatic affections of microbes having equal pathogenic power, as, for example, association of various species of streptococci with one or more of the staphylococci. 4. Accidental association of septic or pyæmic microbes with the microbes of the infectious diseases—typhoid fever, cholera, etc. 5. Association in which the second microbe remains localized, and does not enter into the lesions and symptoms of the original disease. 6. Association in which the secondary microbe dominates; for example, a broncho-pneumonitis in an old localized case of tuberculosis, or miliary tuberculosis following whooping-cough. 7. Association of a pathogenic microbe with another microbe which is habitually innocuous, giving rise to a specific disease. In this group belong certain manifestations of pulmonary gangrene, due chiefly to the staphylococcus aureus united to pathogenic microbes. 8. Association of bacteria with the parasites of bacteria. Such is the association of the bacillus of tuberculosis with the aspergillus fumigatus. 9. Bacteria and tumors. Tumors are the chosen seat of the bacteria. The parasitic nature of epithelial tumors cannot, however, be demonstrated. 10. Association of various parasites of the bacteria with pulmonary mycosis.—*Rivista Internazionale D'Igiene.*

Antifebrin in Soft and Hard Chancre.—Dr. Bazilevitch warmly recommends the treatment of soft and hard chancre by freely powdering it with antifebrin twice daily (every morning and evening). He describes a case of Hunterian chancre in a man of twenty-three, where the ulcer became strikingly cleaner on the third day of the treatment, to completely cicatrize in ten days. In another case, referring to a man aged thirty-six with a large soft chancre, the latter assumed a healthier appearance on the fourth day. On the seventh there appeared sound granulations, the ulcer kindly healing in the beginning of the third week. Similarly good results were also obtained in a case of a woman, aged twenty-five, with hard chancre of the minor labium and uterine cervix. The advantages claimed for the method are these: 1. The lesions heal comparatively very quickly. 2. The remedy is very cheap. 3. It is entirely free from odor. 4. Even when used externally in "enormous" quantities it does not give rise to any toxic or disagreeable phenomena.—*St. Louis Medical and Surgical Journal.*

Cystinuria.—At a recent meeting of the Royal Academy of Medicine in Ireland, Dr. Walter G. Smith read a paper on "Cystinuria." The condition, he said, is a rare one, and scarcely seventy cases are upon record. A boy, aged eight, was reported by his mother to have passed urine of a fragrant, orris-root odor, and depositing a greenish sediment. The boy's health was excellent in all respects, and there were no symptoms of urinary irritation.

Out of six occasions upon which the child's urine was examined, once only was cystin found. The crystals were identified by their form, solubility in ammonia, and insolubility in acetic acid. The true formula of cystin is $(C_3H_6NSO_2)_2$. Dr. Smith discussed in some detail our present knowledge of the physiology and pathology of cystin. The following summary may be given: 1. Cystin, or a cystin-like body, occurs in small amount in human urine as a normal product of proteid metabolism. 2. No relationship exists between uric acid and cystin. 3. Associated with cystinuria, pathologically, is the occurrence, in the urine and fæces, of certain ptomaïnes, belonging to the class of diamines, viz.: (*a*) Penta-methylene diamine (Cadaverin), $C_5H_{14}N_2$; (*b*) tetra-methylene-diamine (Putrescin), $C_4H_{12}N_2$. 4. Normal urine and fæces never contain diamines, nor do they occur in cystin calculi. 5. The formation of diamines is due to the agency of specific bacteria in the intestine. 6. The exact nature of the correlation between cystinuria and diaminuria has not yet been determined. 7. Cystinuria may persist for years without apparent injury to the health of the patient. 8. The therapeutical indication is to disinfect the contents of the bowel.—*Dublin Medical Journal.*

Uratosis.—The term uratosis has been suggested by Sir William Roberts to designate that disordered state of nutrition characterized by the deposition of the crystalline urates in the tissues or fluids of the body. By adopting this nomenclature, several advantages, it is claimed, would follow. First, a distinction would be clearly drawn between the effects of an excess of uric acid in the blood and uric acid precipitated as crystalline urate. What, if any, pathological significance the former condition has is at present unknown. The serious consequences following the latter state are well recognized. Excess of uric acid in the blood is only an exaggeration of a normal state, while deposition of crystalline urates is, in any quantity, a pathological condition. Another advantage claimed is that we would be better able to estimate the relation between the different causes that give rise to uratic deposits. When speaking of "ordinary" gout and "saturnine" gout, we use terms which, in the opinion of Sir William Roberts, would be more truly expressed by "gouty uratosis" and "saturnine uratosis." It being much more likely that the gouty diathesis and lead-poisoning, while differing in other respects, have one tendency or vice in common, viz., the tendency to the deposition of the crystalline urates, or uratosis. The separation of the effects of the deposition of the crystalline urates from simple increase of uric acid in the blood is of importance from a therapeutic point of view. In the former the danger of precipitation, especially in the kidneys, is of a very grave character and calls for immediate treatment. By the employment of alkaline remedies, we are enabled to postpone for a long period this deposition, and thereby gain time which should be employed in combating the essential cause.—*Montreal Medical Journal.*

Treatment of Varicocele.—In a paper read before the Southern Surgical and Gynecological Association, Dr. Lydston, of Chicago, gave the following indications for operation in this disease: 1. Severe dragging pain and reflex neuralgia. 2. Impotence, pseudo or real. 3. Ineligibility for public service, such as army and navy, in some cases. 4. Severe scrotal eczema. 5. Mechanical impediment to manual labor. 6. Noticeable and conspicuous deformity.

The ideal operation for moderate-sized varicoceles is resection of the scrotum. For large varicoceles, it is resection of scrotum with preliminary ligation of the veins high up in their straight portion. Large varicoceles operated upon by resection of the scrotum tend to recur even when the operation is very thoroughly done, hence the author advocates the combined operation. Subcutaneous ligation he believes to be objectionable. The author related a case of hæmidrosis of the scrotum due to varicocele. Subcutaneous ligation was done in this case, and at the same time a urethrotomy was performed. Hemorrhage from the urethra was severe, and lasted for several days. Dr. Lydston believes that varicocele is essentially due to a general tropho-neurotic state, and is inclined to think that the causative rôle of masturbation has been assigned undue importance. Thirty-five operations have been done by Dr. Lydston; with, in the main, excellent results and no deaths. Two cases of resection of the scrotum have recurred. The author insists that too much tissue cannot be removed, and makes use of King's clamp. The cautery operation of Pearce Gould is condemned as the most dangerous yet devised. Dr. Lydston urges the observance of rigid asepsis in all operations on varicocele. —*Virginia Medical Monthly.*

Medicine among the Mongols.—In Mongolia the practice of medicine rests chiefly with the priests or Buddhist lamas, whose system is quite elaborate, but based for the most part on superstition. Instead of paying occasional visits to the patient, their method is to reside in his house until recovery or death takes place, or the case is decided to be incurable. The people have great confidence in drugs and medical regimen, including the water-cure, the latter object causing them to resort to springs, both hot and cold, that are somewhat abundant in Mongolia and Northern China. They place implicit confidence in the medical knowledge of the foreign missionaries who visit their inhospitable country, but express wonder and astonishment when their proffered recompense is refused by the latter. A very frequent affection among the Mongols is the itch, due in a large degree to their repugnance to the washing of either their persons or garments. In their tents they live so closely together that if one of them gets the itch all soon have it. Various other skin diseases are prevalent among them. Rheumatism is of frequent occurrence, and the remedy largely used for that trouble consists of kneading, or a kind of massage; they make use of a "rheumatism stick," a piece of wood so bent that any part of the body can be reached by the patients in their self-application of the kneading process. A peculiar disease called narry, due to their indulgence in their native spirituous liquor, is frequent; the stomach becoming intolerant of food, so that the patient ultimately dies of starvation. For the bite of a dog they apply to the wound a portion of the fur of the animal; literally, "the hair of the dog" is their remedy. They use the loadstone in powdered form as a cure for ulcers, deafness, etc. They attribute many diseases to the influence of the planets and constellations, to offences committed, and to fate. Hygiene or preventive measures do not enter much into their scheme of treatment.—*The Medical Press.*

Observations on Human Peristalsis.—Professor Rossbach has arrived at the following conclusions from a careful study of the intestinal movements in man. 1. In the early morning hours the intestinal peristalsis, as well as the gastric movements, appeared to be at rest. 2. As soon as food is taken into the empty stomach and passes thence into the intestine, an evident peristalsis begins, alternating with intervals of quiet. Sometimes the movements begin within a quarter of an hour. 3. No difference could be perceived in the intensity of action of different articles of diet upon the intestinal movements, except that coffee, whether taken fasting or after midday meal, almost always produced the strongest peristalsis. 4. In general the irritability of the intestine appeared to have grown very slight by evening, since often no peristalsis was to be observed either immediately or for a long time after the ingestion of the evening meal. 5. Except as mentioned, there appears to be no regularity in the intestinal peristalsis. The movements may be present before, during, or after a meal; may be marked or slight; may develop at once after eating, or only after one to two hours. 6. The peristaltic motion never lasts long with the same intensity. Large waves

alternate with small ones, or with intervals of rest. These observations apply to the intestine under the influence of ordinary nourishment only. The author has examined also the effect of various agents upon the movements, with the following results: 1. Slight degrees of cold, as the mere exposure of the abdomen, produce peristalsis after a few minutes, or strengthen it if already present. 2. Greater degrees of cold, as sprinkling the abdomen with cold water, likewise increase the peristalsis only in slight degree. 3. The drinking of cold water produces at once a lively peristalsis. 4. Rubbing the abdominal walls has no effect. 5. Moderate pressure in the space between the two *recti abdominis* is followed by an unusually active movement. 6. Pressure and squeezing of the intestine itself produces no movement. 7. After coughing the peristalsis becomes evidently stronger during a considerable time. 8. Through pressing (evacuation of the bowels) an increased peristalsis is produced. 9. Respiration does not cause an active peristalsis to cease, but a prolonged holding of the breath does have this effect, though the movements returned later. 10. Purgation, accomplished by means of enemata, develops very violent peristaltic movements, accompanied by rumbling and distention of the abdomen. 11. One to two drachms of castor-oil taken internally have no effect upon the bowel during the first half-hour, but then develop active peristalsis combined with rumbling in the abdomen. 12. Intense sensations of hunger always occasion active peristalsis. 13. The excitement of the emotions (as moderate fright, the sudden refusal to allow the patient to eat when hungry, etc.) causes the immediate disappearance of peristalsis, even when strong. After five to ten minutes the movements return. 14. The employment of electrical irritation produces very varying results. (*a*) The faradic current applied to different parts brought out or strengthened peristalsis in a few cases, but its action was very inconstant. (*b*) The galvanic current in like manner usually produces no, or but slight, peristalsis, and only in a few instances, when applied through the rectum, succeeded in developing active movements.—*Deutsches Archiv für Klinische Medizin.*

Hahn's Method of Performing Gastrostomy.—Dr. Eugene Hahn describes his method of performing gastrostomy by fixing the stomach in the eighth intercostal space. He first did the operation in June, 1887. Since then he has performed eight operations by this method. These compare very favorably with the seven cases performed by Fenger's method. The operation is performed by making an incision parallel to and half an inch below the margin of the ribs in the fore part of the eighth intercostal space; a second incision is made in the eighth intercostal space, close to the junction of the eighth and ninth intercostal cartilages, in an oblique direction from above downward. The parietal peritoneum is punctured at this point by forceps or knife, and enlarged by spreading forceps. The thumb and index-finger of the left hand are introduced into the first incision, and the stomach sought for at a point corresponding as nearly as possible to the fundus. This is grasped by dressing-forceps and drawn through the eighth intercostal space, until the stomach projects half an inch beyond the skin. If some days are to elapse before opening the stomach, it is fastened to the skin with sutures which pass through the serous membrane only; but if an immediate opening is necessary, the sutures must go through the whole thickness of the stomach. By experiments on cadavers Hahn found that there was no danger of wounding the diaphragm if the incision were made between the eighth and ninth costal cartilages. The advantages are: 1. A small, contracted stomach is found with great certainty and can be fixed with less dragging. 2. The adhesion seems stronger and more sure than when the abdominal incision is made, and the contents of the stomach do not come into contact with the parietes to the same extent as in older methods. 3. Nutrition is better established, because the food is introduced at some distance from the pylorus; and 4. No obturator or other means of closing the opening is needed afterward, because the proximity of the cartilages prevents the fistula becoming larger.—*Centralblatt für Chirurgie.*

The Duration of Pregnancy.—Dr. Oliver states that the duration of pregnancy in the human female varies as much as it does in the case of many of the lower animals. Issmer, reckoning only cases in which the fœtus was well developed, asserts that the duration ranges from two hundred and sixty to three hundred and four days. But Oliver believes there must be some error in this statement. If we reckon from the last menstruation, we must be careful to ascertain the exact date of the cessation of this, for it will be remarked that where the duration of the discharge varies little, the woman, when asked, is more likely to give the date of the beginning than the date of cessation of the last menstruation, and in this way mistakes may arise in our calculation to the extent of four or more days. The majority of authors are agreed that in reckoning the duration of pregnancy in woman, we ought to fix the probable date of delivery on the two hundred and seventy-eighth day from the cessation of the last menstruation. He is of opinion that the best results will be obtained by ascertaining, first, the date of the cessation of the last menstruation, and then the usual duration of the inter-menstrual period in each given case; the number of inter-menstrual days should then be divided by two, and it will be found that the two hundred and sixtieth day from the middle of the inter-menstrual period will most probably be the date of confinement. —*Liverpool Medico-Chirurgical Journal.*

Milk Diet in Typhoid Fever Overdone.—Dr. Da Costa thinks that the exclusive use of a "milk diet" in typhoid fever is overdone. The stools should be carefully watched to see that the milk does not disagree. His plan is to use three pints of milk and one pint of broth in the twenty-four hours, given alternately, with a mid-day meal of arrow root, or other thickened food. It should be given every two hours during the day, and every three hours at night. In very light cases it may be given every four hours at night, but under no circumstances should nourishment be used less frequently.—*College and Clinical Record.*

Some Points in the Dietetic Management of Children.—Dr. Rachford formulates the following rules, which may aid us in selecting a diet when it becomes advisable to discontinue milk temporarily: 1. Avoid albuminous food, *a*, when marked constitutional symptoms are present; *b*, when in doubt as to the character of the fermentation causing the disease; *c*, when the stools are putrid; *d*, when the stools contain mucus and blood; *e*, when the nausea is constant and not relieved by vomiting. 2. Avoid carbo-hydrates as a food, *a*, when there are no marked constitutional symptoms present, and the stools are continuously acid; *b*, when there is much flatus, pain, or urticaria. 3. When the albumins are to be avoided, the carbo-hydrates are, as a rule, indicated; and when the carbo-hydrates are to be avoided, the albumins are, as a rule, indicated. 4. Give foods, such as cream, beef broths, and whiskey, *a*, when the foods prescribed according to the above rules disagree; *b*, during the first twenty four hours in severe acute cases; *c*, when in doubt as to the character of the food indicated.—*Archives of Pædiatrics.*

Urticaria of the Tongue.—Dr. Bock reports a case of urticaria of the tongue in a patient thirty-eight years of age. The patient was subject to such attacks after eating mussels. The onset of the attacks was very sudden and alarming; the tongue became greatly swollen, the larynx œdematous, and he was unable to speak. Dr. Bock ordered a mustard foot-bath and a hypodermic of atropin, and in a short time the alarming symptoms disappeared.—*L'Union Médicale.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 28, 1891.

FACTS GLEANED FROM LAST YEAR'S GRIPPE.

THE year of grace that included parts of 1889 and 1890 was marked by direful disaster in the way of epidemics. First came the dreadful pest that held sway in Arabia. Yellow fever reigned in Rio Janeiro, carrying off three hundred and forty-seven persons in one month and increasing the death-rate steadily for three consecutive months. Cholera, originating in the Philippines early in the year, soon reached Madras and all of British India, attacking Mesopotamia in the summer and threatening all Europe. Dysentery raged in Galicia, and carried off about ninety-five of every one thousand of the population. Small-pox appeared in various parts of Egypt and in Sardinia. Typhoid fever in Basle caused the death of two hundred and sixty-two persons in a fortnight. In the Vienna Maternity, thirty women died of puerperal fever. Beriberi raged with unusual intensity in Brazil, causing the death of one hundred and eleven persons in Rio alone. Then came grippe, from which the world has not yet entirely recovered, epidemics having reappeared this year in New York, New Orleans, Pittsburgh, Chicago, and Sumatra. What has been, may be again; and in view of the fact that these places suffered severely during the pandemic of 1889-90, vigilance now may do something to secure some immunity in other localities, as unhygienic surroundings increase the severity of the disease, however and by what it may be caused.

In a paper on grippe read by one of the women physicians before the New York Academy of Medicine, January 21, 1890, it was suggested that a generous contribution to medical literation could be formed from carefully and concisely worded *résumés* of each practitioner's professional experience of the disease in question. If every form of the epidemic were described and the order of its visitation noted, it would remain to be seen whether cycles of epidemics really exist; which is not impossible if such conditions are connected with telluric or electric influences that are known to observe a periodic course. As ideas are in the air as well as epidemics, this particular thought in regard to records and comparisons occurred to one having authority, General William W. Averell, U. S. A., and was worked out by him with skill and precision. The results are embodied in his report, dated July 1, 1890, made to General Franklin, the president of the board of managers on inspection of national military homes and soldiers' homes in the different States. In answer to special inquiries concerning grippe as it appeared, was treated, and ran its course in these places, many interesting facts have been collected. The chronological history of its recent visitation, together with the number of persons attacked, and the number of deaths, is as follows:

Location.	Date of appearance.	Number afflicted.	Percentage of numbers.	Date of disappearance.	Duration in days.	Deaths.
Bath, N. Y.	Dec. 20, 1889	323	28.0	March 29, 1890	100	
Quincy, Ill.	Dec. 25, 1889	....	10.0	Feb. 15, 1890	55	
Milwaukee, Wis.	Jan. 1, 1890	201	10.0	March 15, 1890	63	1
Marshalltown, Iowa	Jan. 1, 1890	175	50.0	April 15, 1890	105	
Waupaca, Wis	Jan. 1, 1890	50	63.0	March 25, 1890	84	
Minneapolis, Minn	Jan. 2, 1890	27	19.0	April 6, 1890	95	
Sandusky, Ohio	Jan. 2, 1890	350	50.0	April 20, 1890	109	
Norfolton, Conn	Jan. 3, 1890	150	68.0			
Togus, Me.	Jan. 3, 1890	364	20.0	Feb. 20, 1890	49	1
Grand Rapids, Mich	Jan. 6, 1890	575	92.6	March 20, 1890	73	
Yountville, Cal	Jan. 6, 1890	8	....	.....	....	3
Leavenworth, Kans.	Jan. 12, 1890	79	4.4	March 4, 1890	52	
Bennington, Vt.	Jan. 12, 1890	20	33.0			
Dayton, Ohio	Jan. 18, 1890	400	8.3	Feb. 15, 1890	29	
Santa Monica, Cal.	Jan. 21, 1890	7	...	March 15, 1890	52	1
Erie, Pa.	Jan. 24, 1890	101	26.0	Feb. 19, 1890	27	
Grand Island, Neb.	Feb. 11, 1890	6	10.0	Feb. 19, 1890	9	

The total number of persons attacked was 2,486, this being an average of nearly thirty-three per cent. of the whole number of soldiers in the various homes. The average duration of the disease was about sixty-five days. There were only six deaths. Treatment, aside from the relief of such symptoms as pain and cough was mainly tonic and sustaining. The remedies most used were preparations of Peruvian bark, strychnine, alcoholic stimulants, and phenacetin. The surgeon in charge of the hospital at Santa Monica states, that preceding, during, and following the outbreak of epidemic influenza, various morbid manifestations appeared in certain persons, less severe in form than grippe, but probably due to the same epidemic influence, such as obstinate neuralgias of the fifth cranial nerve, notably of its superior vital branch, and catarrhal affections of the respiratory tract. The physician in charge at Togus says that in eighty per cent. of his cases (364) distressing bronchial symptoms were present by the end of the second or the beginning of the third day, consisting of a feeling of soreness and tightness across the chest accompanied by a hard, dry cough. Unless stimulated by drugs, expectoration was not established for two or three days. The cough often lasted for two or three weeks. Next to the profound physical depression, cough was the most persistent and troublesome symptom. In not more than five per cent. of the cases was there any involvement of the nasal or pharyngeal mucous membrane. The whole force of the disease seemed to expend itself upon the nervous system in about fifteen per cent. of those attacked. There was one case of grippal paraplegia lasting two weeks; one case of paralysis of the larynx and of the muscles of the left side of the face; and one patient had acute maniacal delirium for a fortnight. Organic heart or lung trouble, four cases in all, was brought to a fatal termination by the onset of grippe.

While all the information in General Averell's report is valuable, the most interesting and instructive record concerning grippe is that furnished by R. Humphrey Stevens, the surgeon in charge of the Michigan Soldiers' Home Hospital. The disease appeared there as one of

lassitude and prostration, followed by fever and pain either in the head, chest, or back. Then the malady presented itself or passed into one or all three of the following forms: First, affecting the sensory nerves; second, affecting the mucous surfaces; third, affecting the muscular system.

Of the first class there were 351 cases; of the second, 153; and of the third, 71; total, 575. Of the first class, 323 were cured, and 27 developed into glandular inflammation. All cured. Of the second class 147 cases were stopped at the outset, and 13 cases developed pneumonia. All cured. Of those cases affecting the sensory nervous system and not developing into glandular inflammation, 2 had irido-choroiditis and 2 had idiopathic herpes. The other 320 had neuralgia of the trifacial and its branches, with great pain unaccompanied by swelling. Glandular swellings were confined to the lymphatics of the throat and neck except in two cases, in one of which the glands of the groin were affected and the other suffered from orchitis, making a total of 351 cases.

Of the second class, 140 were of a typical nature, experiencing profuse mucous discharges that were sometimes purulent. Those of this class that developed into pneumonia presented the following characteristics: 1 double pneumonia, 12 single, 8 on left side and 4 on right side. The kidneys were complicated in 18 cases, of which one case had pneumonia and none had diarrhœa. Of the third class, 71 cases, 68 were to all appearances incipient inflammatory fever, of which three developed into typical forms. All recovered. No age was exempt. The younger men suffered most from pyrexia and pain. Among them occurred all the cases of pneumonia except one, in which instance the severity of the symptoms was greatly aggravated by previous intemperance and exposure.

Primary symptoms of grippe appeared January 6, and disappeared March 20, 1890, the secondary symptoms disappearing May 28, 1890. Dr. Stevens's careful record of typical cases presents the following average pathological facts: First day: Respiration normal, pulse regular, bowels regular, urea deficient. Second day: Condition same, except urea decreasing. Third day: Feels languid, dumpy headache; evening headache intense; urates and uric acid in urine, urates in abundance. Fourth day: Pulse 130, temperature 103; intense pain in head and back; urine scanty, specific gravity 1024; urates, uric acid, and oxalate of lime, chlorides abnormal. At 2.30 P.M. broncho-pneumonia appeared. Fifth day, 5 A.M.: Pneumonia decided; expectoration; urine same, except chlorides disappear. As the fever increases the specific gravity of the urine increases, and with the increase in urea there is increase of urates until finally the urine is acid, and crystals of uric acid, urates, and oxalates appear. In a case presenting all these features, inflammatory fever usually sets in, especially if the patient has a tendency to the rheumatic diathesis. The patient does not always enter the first class of disturbances first, but may begin his grippal condition with the second or third stage and develop the others later. A case unchecked or unrestricted by treatment almost invariably passes through the three forms sooner or later.

While collecting from cases data for physico-chemical facts, a climato-metrical record was kept, of which Dr. Stevens states that the variations compared identically with the number of cases of grippe that appeared. The condition of the system produced by these climatic changes resulted from an absence of electricity, or rather an electro-negative condition of the air, a great decrease in atmospheric ozone, an increased amount of moisture, a higher temperature, and a higher barometric condition, all acting or existing in an uncommon or unusual relation to each other. In other words, grippe is a disease of deoxidation from causes external to the body *per se*, and varies according to the oxyo-galvanometric and barometric condition of the air breathed. Expressed mathematically, its prevalence is proportional to the increase in weight and humidity, and inversely to the amount of ozone and the electrical condition of the atmosphere.

In view of the intense nerve depression resulting from uneliminated organic excrementitious products existing in abundance in the blood, and which all the reserve nervous force of the body endeavors to throw off and burn up, the too popular antipyretic sedative treatment is unwarrantable and unscientific. Fatal prostration and heart failure in grippe are probably due more often to drugs than to the disease itself. In the Michigan Home Hospital, with its five hundred and seventy-five cases, more benefit was derived from tonic eliminative remedies than all else, from hot air and hot water, externally and internally, followed by anti periodic alkaloids.

THE REGULATION OF PROSTITUTION.

The discussion of the subject of licensing prostitutes and regulating prostitution has again become a subject of present interest. The Legislature of Missouri has before it a bill providing for the regulation of prostitution. At the International Medical Congress, Dr. Thiry read a paper on the subject, which excited much discussion, and quite recently it has been brought up before the New York Academy of Medicine. We notice also that even in so remote a land as Japan there has been an agitation started, and the Imperial Diet has been memorialized by a large number of citizens, who ask for the abolition of the license system and present statistics showing that it is a failure in Japan.

Those who assert that the licensing system should be established produce statistics which show that it reduces the amount of venereal disease. For example, in France, M. Commenge has recently stated, at a meeting of the Academy of Medicine of Paris, that he had collected the statistics of the number of diseased prostitutes found in the decade from 1878 to 1887: First, among women registered by houses or cards; second, among those women that—though registered—were the object of more or less frequent arrests, and constituted a special class under the name of *femmes du dépôt*; third, and lastly, among the uninspected, or women that lived by clandestine prostitution. The results obtained, based on nearly a million visits, showed the number of cases of syphilis in each thousand examined to be respectively 3.1, 2.7, and 23.9. Of other venereal diseases 3.0, 2.5, and 14.5.

Thiry, of Brussels, gives similar figures. The Vienna syphilographers are all naturally in favor of regulation. Neumann would have prostitution entirely under government control. Prostitutes should, according to him, be

regularly examined, and if diseased quarantined. Soldiers, sailors, and even factory hands and wet nurses, should also be regularly examined. Already in Vienna each prostitute receives a book containing a description and photograph of herself, and a copy of the laws relating to prostitution. No one under sixteen can be registered, no persons afflicted with organic or constitutional disease. Sanitary examinations are made twice a week, all diseased women are put into hospitals, primary syphilitic cases are quarantined for three months, and kept under treatment for two years. Clandestine prostitutes are treated in the same way by their own physicians.

The results of this treatment in Vienna are not dwelt upon with so much enthusiasm as the methods. Vienna is rank with venereal disease. The idea that continence is a moral virtue, simply does not exist for men or for lower-class women, half the births in the city are illegitimate, and Austria's Crown Prince shoots himself as the result of a low intrigue. Statistics are brought forward by the opponents of licensing which appear to show that the system is a failure in Paris, Berlin, Italy, and Great Britain. The statement of Lacour, chief of the police of Paris, that licensing does not protect and that prostitution cannot be made safe, is also often quoted.

It seems, therefore, that judgment must be formed upon general principles, since the facts are so inadequate.

One general principle, viz., that the sexual propensity cannot be regulated by law, seems to be a pretty safe one. If there is a general desire in a given community to do a thing, it will be done. Regulating prostitution, however, is said to make this indulgence safer. Facts do not quite prove it. Furthermore, it is admitted that all attempts to register and examine prostitutes thoroughly have failed. And for our part we should dislike to feel that members of our calling would accept so low and despicable a position as that of government examiners of prostitutes.

A mistake which advocates of the licensing system make is that of considering the question solely as a sanitary one. Even if it were proved that syphilis were reduced five per cent. in a given community, it would not prove that the community was a happier or healthier one. For under the stimulus of a government assurance that prostitution was safe, the amount of illicit indulgence might be doubled, with the result of increased domestic trouble and moral degradation.

The injustice of forcing women to be examined, and not men, has often been referred to. M. Thiry considers this a "fallacious idea," though upon exactly what grounds he fails to state.

It has seemed to us, taking all the facts into consideration, that the safest method of treating the subject of prostitution is the educational one. Its moral and physical dangers should be assiduously inculcated, especially upon the rising generations.

THE PATHOLOGY OF DIPHTHERIA.

It is pleasant to find that certainty has been reached in any department of medical science. Particularly is this the case in reference to so dangerous and intractable a disease as diphtheria.

In 1884 Löffler anounced the discovery of a bacillus which he thought was probably the specific cause of this disease. His statements were cautiously made, however, and his conclusions were provisional. In a subsequent essay, published last year, Löffler reviews the work of other bacteriologists upon this subject, and shows that they have all invariably succeeded in finding the so-called Klebs-Löffler bacillus in primary diphtheria. From their experiences in studying this bacillus he concludes that there can no longer be any doubt of its specific character. It has been determined also that this bacillus, though always present in the diphtheritic deposits, does not invade the blood or organs, or even the mucous membrane affected, but that the constitutional symptoms and organic changes are caused by a toxic albumin.

We have said that the results of investigations have been uniform. One exception must be made, however. In 1889 Dr. Prudden made a bacteriological study of twenty-four cases of diphtheria occurring in this city, and in not a single instance did he discover the Klebs-Löffler bacillus. Dr. Löffler refers to this apparent hiatus in the evidence, but says that in his opinion further investigations would clear up this contradiction. Professor William H. Welch and Dr. A. C. Abbott (*Bulletin of the Johns Hopkins Hospital*) have recently undertaken such investigations.

They made bacteriological examinations of eight cases of primary diphtheria, and found the Klebs-Löffler bacillus in every instance.

They also made some control experiments upon cases of simple tonsillitis or pharyngitis, and upon secretions from healthy throats, but failed to find the specific bacillus.

The only species of bacteria which was found constantly in the cases of diphtheria was the Löffler bacillus. Two other species were present in many cases, viz., the well-known streptococcus, which grows in much smaller colonies and less rapidly than the Löffler bacillus, and a short oval, often slightly pointed bacillus, growing in long chains running parallel to each other. There are, our authors add, often marked irregularities in shape, and especially in size, of this bacillus, even of individuals in the same chain. The colonies of this organism are grayish-white, moist, larger than those of the streptococcus, but smaller than those of the Löffler bacillus. The colonies of this short bacterium bear more resemblance to those of the Löffler bacillus than any others which we have met with, although colonies of other organisms bear a greater similarity in rapidity of growth and in size, notably those of a large coccus, but they are readily distinguished by a more opaque white appearance.

Professor Welch affirms that "every postulate necessary to prove that the specific cause of primary diphtheria is the Klebs-Löffler bacillus has been fulfilled, and that this bacillus may be designated the *bacillus diphtheriæ*. This bacillus is present in every case of primary diphtheria, in such number and situation as to explain the local manifestations of the disease; it can be readily isolated in pure culture, and a disease identical in all respects with human diphtheria can be produced experimentally by the inoculation of pure cultures. The investigation of the toxic albumins, produced by this remarkable bacillus, has cleared up many obscure points.

"The only points which can be brought forward as tend-

ing to cast any doubt upon the recognition of this bacillus, as the specific cause of diphtheria, are the very exceptional observation of an apparently identical bacillus in the throat of healthy children, and the more frequent observation of a bacillus, usually called the pseudo-diphtheritic bacillus, which differs from the true bacillus diphtheriæ chiefly or only by the absence of pathogenic properties when inoculated into animals."

The contradictory experiments of Prudden are explained, not very satisfactorily, by assuming that his cases were not those of primary diphtheria. While this may answer for some, it can hardly be supposed that it will do so for all.

THE CONTINUOUS EMPLOYMENT OF SULPHONAL IN PSYCHOSES.

Among the newer hypnotics, sulphonal appears to be holding its own remarkably well. Quite an extensive literature has already sprung up relating to this drug, which was added to our medical armamentarium only two years ago. While many observers have recorded only gratifying results from its use, others have expressed themselves in a less enthusiastic way, and retain their preference for chloral and opium.

Umpfelbach (*Therapeutische Monatshefte*) thinks chloral more certain in its effects. Garnier (*Annales Médico-psychol.*) says that sulphonal insures sleep, but does not quiet patients in the day-time. Knoblauch (*Therapeutische Monatshefte*) is far from pleased with its employment.

Prominent among those who are strongly impressed by its excellent hypnotic properties are Kast, Rabbas, Rosin, Oestreicher, Cramer, Schwalbe, Normann, Otto, Jastrowitz, Pachoud and Claret.

The most recent contribution to the subject is published by Dr. Vorster in the *Allgemeine Zeitschrift für Psychiatrie*. The author has had considerable experience with sulphonal, having used about three hundred ounces of the drug in fifty-six cases of mental disease, the patients being inmates of the insane asylum of Königslutter. He says that its systematic exhibition results in sleep at night and pacification by day. Motor explosions are suppressed by sulphonal, and this accounts for some unpleasant phenomena occasionally observed, such as staggering gait, vertigo, difficulty of speech, and weakness of the extremities. It is pre-eminently a motor depressant.

In hallucinations accompanied by fear and similar psychoses, its good effects are less apparent. In acute and chronic mania, in senile dementia, in progressive paralysis, idiocy, and epilepsy, perverted motor manifestations were almost invariably held in complete control. The daily dose required to insure its efficacy was rarely sixty grains; generally thirty grains were found sufficient. In acute mania or melancholia, the author asserts that, sulphonal is as beneficent in its action on the brain, as an aseptic dressing on a fresh wound.

Symptomatic improvement in cases of severe epilepsy was also observed by Dr. Vorster under the systematic administration of sulphonal.

"Sulphonalism" was at times observed by the author. He states that this condition shows two stages, first a motor-depressive, and second, a sensory-depressive one. He never saw sulphonalism develop after a single dose of the drug. As this part of the subject has received little or no attention in our country, we will follow the author in his description of the two stages mentioned.

The first stage is characterized by motor disturbances resembling paretic weakness. The lower extremities are first affected, the patient's gait assuming a staggering character. Next the tongue, and still later the arms, participate in this weakness.

As regards the second stage, the symptoms resemble those of sopor. The patient is drowsy, he can be wakened by a loud voice, but presently falls asleep again. Sensibility to pain is lessened. Cutaneous reflexes are absent, but the tendon reflexes persist. In taking food the patient requires assistance.

The author says that the first stage is devoid of danger, but the supervention of the second stage carries a warning with it that too much sulphonal has been used, especially as cardiac weakness has been noticed while it lasts.

Dr. Vorster has witnessed no unpleasant symptoms on discontinuing sulphonal after its daily employment for weeks and months. Phenomena analogous to morphinism were never observed.

On the whole, we are disposed to agree with the author that sulphonal is a valuable remedy, and that its employment in disturbed mental states deserves a further trial.

EXPECTANT OR OPERATIVE TREATMENT IN TUBERCULOSIS OF JOINTS.

In a series of articles on this subject Dr. Watson Cheyne (*The Lancet*) considers the rival claims of treatment on the expectant plan and active surgical interference in cases of tubercular joint disease. His views may be summarized as follows: Operative interference is desirable in the following cases: where chronic suppuration has occurred; at an early stage, where the disease is localized to one part of the synovial membrane or bone; in many cases, at a later stage, where there is a deposit in the bone along with general synovial thickening; in cases of diffuse synovial thickening, where expectant treatment has failed to arrest the progress of the disease; in cases where a better functional result can be obtained by operation; in cases, in adults, where deformities are present which can only be remedied by operation; in many cases where there are septic sinuses; in certain cases where phthisis is present, or the general condition such as to require removal of the disease; in adults more frequently than in children; in the poor more frequently than in the rich.

Expectant treatment should be employed in the first instance, in cases of diffuse synovial disease without suppuration, provided that there are no other reasons requiring operative interference, and it should be persevered in so long as improvement follows; also at first, in cases in children where osseous deposits are present in parts where they cannot be reached without excision, or in cases where the presence of deposits in the bone is doubtful; also in some instances where septic sinuses are present. In any case it should be persevered in longer in children than in adults.

It will thus be seen that he limits the sphere of expectant treatment considerably, and this limitation is mainly due to the fact that, under aseptic precautions, we can now cut into joints at an early stage, while they are as yet comparatively healthy, and remove portions of synovial membrane or bone without fear of doing harm by our operation, and with a good chance of ridding the patient of his disease and getting a useful joint. The cures by expectant treatment, when it is carried to excess, are often obtained only at a great expenditure of time, and after great endurance of pain and at a certain risk to the patient; and it by no means follows, because a good result is obtained in any given case by expectant treatment, that it would not have been wiser, and that in a number of similar cases the results would not have been on the whole better, had operative measures been employed.

He concludes as follows: "In thus attempting to indicate the limits of expectant and operative treatment, I am well aware how far I have come short of what is wanted; but in these diseases, perhaps more than in any other, so many points have to be taken into consideration, and so much depends on the circumstances of each individual case, that it is quite impossible to lay down rules which are universally applicable; and one cannot do more than indicate some of the chief points which must be taken into consideration in coming to a decision."

News of the Week.

The Profession and the Secular Press.—At the meeting of the Medical Society of the County of New York held on Monday evening, Dr. Fred R. Sturgis read a paper on the question, "Under what Circumstances and to What Extent May Members of the Medical Profession Properly Permit their Names and Opinions to be Published by the Secular Press?" Drs. A. Jacobi, Daniel Lewis, A. S. Hunter, George F. Shrady, and D. B. St. John Roosa took part in the discussion. While it was acknowledged that it was proper to inform the public on medical matters of general interest, the practice of advertising the individual man as possessing special skill in the treatment of disease, etc., was severely criticised. The doctor was privileged on proper occasions to speak for the profession, to quote its opinions or give its conclusions, but not to magnify his own importance at the expense of his brethren. A fuller report will be published at a future time.

Death of Dr. W. B. Sprague.—Dr. William Bishop Sprague, who died at his home at Pavilion, Genesee County, N. Y., last week, aged fifty-five, was a native of that town, and was graduated in his profession from the Buffalo Medical College in the class of 1857. He succeeded his father in practice at Pavilion. He became a member of the State Medical Association and President of the Genesee County Medical Society. In 1887, on account of ill health, he left his home practice and took the post of surgeon of the New York and Amsterdam steamship Rotterdam. He returned home from this post prostrated by the malady which caused his death.

Medical Attendance on the Indians.—The *New York Times* says: "A portion of the Government's reservation system for the red men which seems susceptible of improvement is that which concerns their medical treatment. The civilized tribes make their own provision for this purpose, while for the others the Government furnishes in all eighty two physicians and surgeons. Tribes small in numbers or occupying a very limited area doubtless find a single agency physician sufficient; but this can hardly be the case with a tribe which has eighteen thousand people living on a reservation of twelve thousand square miles, with but one Government doctor to attend to them. There is also lack of general supervision, although many of the physicians are known to be men of fidelity and good professional attainments, and, in fact, all are required to have testimonials to character as well as a diploma from some reputable medical school. But the salaries are meagre, only one physician getting as much as $1,300 per year, while $1,200 and $1,000 are the usual rates; and there are, of course, fewer aids to practice than elsewhere, while the lack of hospital accommodations is particularly marked. Like several other features of the Indian system, this one seems to have grown up in rather a makeshift way. Perhaps more improvement might be made in it were the whole reservation system itself likely to last very long."

Bequest for a New Hospital.—In the will of John H. Krause, recently probated in Philadelphia, is contained a bequest of $20,000 to the King's Daughters of Pottstown, Pa., for a hospital, to be conducted under the management of the society, provided the society shall make up a like amount.

Dr. Jacques died at his home in Manchester, Conn., last week, aged sixty-nine years.

State Care of Inebriates.—The Legislature of the State of North Carolina has set aside a portion of the Western North Carolina Hospital for the care and treatment of inebriates. This is looked upon as only a beginning of what will ultimately be a duly appointed and properly equipped asylum.

Dr. N. Senn, of Milwaukee, has been appointed Professor of Surgery in the Chicago Medical College.

The Graduating Age in Medicine.—In the Seventh Report on Medical Education, just issued by the Illinois State Board of Health, is a paragraph that reads as follows: "Under the schedule of two-year courses and three years' study the earliest age at which a student can be graduated is twenty-one years. The addition of one year each to the time of study and the college term would seem to justify the limitation of the minimum age of graduation to twenty two years. This is a matter that the boards of examiners and the colleges would do well to take under consideration." Following this paragraph is a table showing the ages of graduation of 5,719 graduates—5,497 of American collegess, 82 of Canadian, 32 of English, 98 of German, and 10 of Swiss colleges. Of the 5,497 American graduates 5,214 were males and 283 females. Of the total graduates from twenty-one to thirty years of age, the percentages at different ages are: Twenty-one years, 6.43; twenty-two years, 11.34; twenty-three years, 13.35; twenty-four years, 13.52; twenty-five years, 13.11; twenty-six years, 10.85; twenty-seven years,

9.94; twenty-eight years, 8.54; twenty-nine years, 6.92; thirty years, 5.91.

Surgical Perfection has been attained in one direction, according to Dr. Stephen Smith, who says, speaking of the ligature of arteries: "To one who has been personally familiar with the painful anxiety with which the earlier surgeons watched their cases, especially at the period of the separation of the ligature, such language seems preposterous. But, fortunately, it is true. We have reached the happy era of surgery when to ligate an artery means to strengthen it at the point of ligation. We can ask no more. The improvements in this branch of surgical practice have attained—perfection."

State Examinations of Physicians.—We learn from the *Deutsche Med. Zeitung* (January 5, 1891) that during the year 1889–90, 794 physicians were examined by the Royal Prussian Board of Examiners, of which 184 passed as "satisfactory," 357 as "good," and 22 as "very good," while 231 were either rejected or withdrew. If fifty per cent. of our graduates could thus be weeded out how much more freely would those breathe who, by dint of hard study and careful preparation, have become entitled to undertake the responsibility of leading their fellows to life or death.—*Dietetic Gazette.*

Dr. Lorenzo Hale retires from the editorship of the *Albany Medical Annals*, and is succeeded by Dr. W. G. Macdonald.

An Interesting Exhibit.—The *Journal of the Arkansas Medical Society* wants to exhibit at the World's Fair some of the Arkansas doctors, together with some of their work; also a few hundred death certificates of persons who have died of absolutely preventable diseases, and whose lives would have been spared if there had been a working Board of Health to take charge of the public health.

Dr. Clements, of Yell County, Ark., has introduced a bill providing for revoking a doctor's license if he is guilty of unprofessional conduct, such as committing abortion, advertising to cure palpably incurable diseases, accepting a fee in advance on promise to cure such diseases, employing drummers, etc. We hope our confrère from Yell County will succeed with his bill. It has already passed the House.

An International Homœopathic Congress is to be held at Atlantic City, June 16th.

Suicide of a Physician.—B. M. Pahl, of Findlay, O., committed suicide on March 23d, by taking fifty morphine pills.

Dr. Nathan Camp, of Troy, N. Y., died on March 23d, aged seventy-two years.

A Writer in the *Medical Age* suggests that the *Journal of the Association* be abolished, and the membership fee reduced to the actual expenses of the Association.

Vaccination in France.—The French Academy of Medicine is just now the scene of a struggle between those who are in favor of a law making vaccination compulsory, and the others who think that the present permissive system goes as far as is consistent with personal liberty. Professor Le Fort, who favors the "volunteer" method, argues that, though vaccination has an undoubted and valuable influence in affording protection and in mitigating the severity of the disease, the most effective and reliable means of preventing the spread of the disease is rigorously enforced isolation.

Something New in Bones.—Dr. M. Sternberg has found something new in human osteology. It is only a little hole in the sphenoid bone, which he calls the "canalis cranio-pharyngeus." It is best seen in the skull of a child four years of age.

Richmond's Physicians for the Poor.—After persistent effort on the part of the Richmond Academy of Medicine and Surgery, the City Council has finally elected four physicians—one for different sections of the city—to attend the calls of the needy poor of the city who may be sick at their homes. The salary of each is $600 a year, beginning March, 1891.—*Virginia Medical Monthly.*

Negro Physicians.—The fifteenth anniversary of the Meharry Medical Department of Central Tennessee College was held February 19th. The *Nashville Journal of Medicine and Surgery* says that more than one-half of the educated colored physicians of the Southern States are graduates from Meharry College. With scarcely an exception, they have been cordially received by the white physicians, who have consulted with them in dangerous cases, and assisted in difficult surgical operations.

The Forty-first Commencement of the Medical Department of the University of Nashville, and the sixteenth of the Medical Department of Vanderbilt University, were held in Masonic Theatre on the evening of February 27th.

State Care of the Insane.—The bill appropriating $454,000 to carry into effect the law for the State care of the insane has been approved by the Governor. The board for the establishment of the asylum districts is required to apportion this money in such a way as to provide for the accommodation of 150 patients at the Utica Hospital, 200 at the Hudson River Hospital, 200 at Middletown, 150 at Buffalo, and 127 at Binghamton.

Hypnotism in Public Forbidden.—The first official suppression of a public hypnotic entertainment in this country occurred at Cincinnati, where the Health Commissioner, Dr. J. W. Prendergast, advised the licensing authorities of that city that hypnotic exhibitions should be forbidden. Dr. Prendergast takes the ground that the indiscriminate application of hypnotism is in a large proportion of cases injurious to the mental health of the subjects. The Common Council has interdicted these exhibitions, and adopted an ordinance making them a misdemeanor.

Verdict Against a Health Officer.—The Board of Health of the town of Franklinville, N. Y., brought suit some time ago for damages against Dr. J. W. Kales, of that place, alleging that he had failed to report a case of malignant diphtheria. Dr. Kales claimed that the case was one simply of follicular tonsillitis, and has fought the Health Board in the courts, asserting that the prosecution was more in the nature of a persecution. The Supreme

Court has now granted a non-suit, and the Health Board has all the costs to pay. Dr. Kales is to be congratulated upon having successfully maintained his rights.

Medical Matters in the Northwest.—A correspondent from Portland, Ore., writes: "Medical matters in this northwest corner keep pace with our other rapid improvements. We have three hospitals besides the county farm, two medical colleges, a State and city medical society, blatant advertising quacks, corruption in politics, and Koch's lymph. The first injection of the latter was given yesterday, and it took nearly two columns in one of our daily papers to describe it."

Physical Examinations in Damage Cases.—The interesting question whether the courts have a right to order the physical examination of a plaintiff in an action for personal injuries, without regard to its being consented to or not, has been lately considered by the Alabama Supreme Court, and a decision given in favor of the rule allowing such an examination. After discussing the weight of authority the Court held the following propositions to be established: "First. That trial courts have the power to order the surgical examination by experts of the person of a plaintiff who is seeking a recovery for physical injuries. Second. That the defendant has no absolute right to have an order made to that end and executed, but that the motion therefor is addressed to the sound discretion of the Court. Third. That the exercise of that discretion will be reviewed on appeal and corrected in case of abuse. Fourth. That the examination should be ordered and had under the direction and control of the Court, whenever it fairly appears that the ends of justice require the disclosure or more certain ascertainment of facts which can only be brought to light or fully elucidated by such an examination, and that the examination may be made without danger to plaintiff's life or health, and without the infliction of serious pain. Fifth. That the refusal of the motion where the circumstances present a reasonably clear case for the examination under the rule last stated is such an abuse of the discretion lodged in the trial court as will operate a reversal of the judgment in plaintiff's favor."—H. E. Riley, in *New York Medical Journal.*

A Cure for Hawking due to accumulation of inspissated mucus in the naso-pharynx is, according to the *Omaha Clinic*, the following:

℞. Ammon. muriatis,
Pulv. ext. glycyrrh. .... āā ʒ ij.
M. F. pulvis.

Of this two teaspoonfuls are taken in a glassful of water on an empty stomach in the morning, every two hours during the day, and the last dose before retiring. This is continued until one single attempt at clearing the throat will cause an easy and loose expectoration, when the frequency of the dose is reduced first to every three, then to every four, and finally five hours.

The Late Dr. Hosmer Allen Johnson.—The following resolutions were adopted by the Faculty of the Chicago Medical College at a meeting held on February 28, 1891:

Resolved, That by the death of Hosmer Allen Johnson, M.D., LL.D., the Chicago Medical College has lost the services of one of its founders and most active, able, and eloquent teachers; the Northwestern University one of its wisest trustees and councillors; the medical profession one of its most learned, honorable, and influential members; and the community one who for nearly forty years has been an active, skilful, and untiring benefactor to the suffering, alike in peace and war, and in the direst of conflagrations.

Resolved, That to his bereaved family and friends we tender our most sincere and abiding sympathy, and the assurance that their temporal loss is his eternal gain.

Resolved, That the Secretary of the Faculty furnish a copy of the foregoing resolutions to the family of the deceased, and to the medical and other periodicals of this city.

N. S. Davis, M.D., LL.D.,
Edmund Andrews, M.D., LL.D.,
Ralph N. Isham, A.M., M.D.,
Committee.

The Charter of a Medical College Repealed.—The bill presented at the instance of the New Jersey State Board of Medical Examiners, repealing the charter of the Medical and Surgical College of that State, has been passed by the Legislature and approved by Governor Abbett.

Dr. H. A. Wilson has been appointed Lecturer on Orthopedic Surgery in the Jefferson Medical College, of Philadelphia.

The Medical Society of the Missouri Valley held its third annual session in Omaha, Neb., on March 19th and 20th, 1891.

An Institute of Preventive Medicine was recently opened in St. Petersburg with considerable ceremony. The institute was established by Prince Alexander Petrovitch, of Oldenburg, who gave upward of $100,000 for the purpose. Pasteur, Koch, and Lister had been invited to be present at the opening ceremonies, but being unable to accept, sent each his representative.

Yellow Fever in Lyons.—There have recently been four deaths in Lyons from yellow fever, the explanation of the occurrence of the disease, as given by a local paper, being a curious one. It appears that a young married couple came from Marseilles to a house in the suburbs of Lyons to visit an aunt of the husband, and brought with them a present for the old lady in the shape of a pair of paroquets, which had been bought from a sailor just returned from South America. A few days afterward the young couple, the aunt, and a servant, all the inhabitants of the house, were seized with an illness that puzzled greatly the physician called in to see them. On consultation, however, it was decided that the disease could be no other than yellow fever, and despite all the care of the physicians, the patients soon succumbed. The medical attendants regarded the paroquets as the carriers of the infection.

International Congress of Otology.—The next meeting of the International Congress of Otology, which had been fixed to take place at Florence in September, 1892, has been postponed until 1893, when it will be held at Rome, a week before the assembly of the Eleventh International Medical Congress.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting. March 19, 1891.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

A Contribution to the Study of Malaria in New York.—DR. WALTER B. JAMES opened the discussion on this subject with a paper. It was based on a study of four hundred cases which were supposed to be largely malarial, the study being in the light of recent knowledge regarding malarial diseases. According to this knowledge true malaria was due to a living animal organism, of characteristic appearance, easily distinguished from all other organisms in the human body found in the blood; in the more acute cases it was a minute amœboid body, containing pigment; in the more chronic cases it was seen swimming about in the blood—a round, crescentic, or oblong hyaline body. He had himself studied the disease as it had been acquired on various parts of the globe, and in all the microscopic appearance of the blood was the same. At the time of the paroxysm one always found a certain number of the protozoa in a state of reproduction. These forms were not found at any other time, and it seemed very probable that the paroxysms were brought on by the ripening, as it were, of the organism.

We were yet unable to say whether there were two distinct varieties; it might be that they were only the developmental change of the same species. This supposition was entirely consistent with what was known of other similar creatures. The author believed, therefore, that we were justified in assuming that malarial disease, however acquired, was the result of a specific organism which existed in the blood, perhaps in other parts, and that a differential diagnosis could be made by examination of the blood.

An enormous amount of literature existed with regard to the soil, climate, etc., in their relation to malaria, but a careful review of it convinced the reader that this phase of the subject was still vague and unsettled. The only way which we yet had to determine whether a given spot was malarial was to put people there and see if they got malaria. There was nothing in the geology of Manhattan Island which would enable us to say whether it would be likely or unlikely to be malarial. This question would have to be determined by clinical observation and microscopical examination of the blood. But anywhere where the disease did exist, it was more likely to occur, or to occur with greater frequency, when the soil had been freshly dug up.

Classifying the four hundred cases clinically in which he had examined the blood during the past four years, there were—1, Cases of fever of an intermittent type; 2, cases of fever of a remittent type; 3, cases of disease other than malaria, but with a supposed malarial element; 4, cases of cachexia; 5, headaches, neuralgias, malaise, etc., of such degrees and periodicity as to suggest the possibility of malarial origin.

Regarding the first class of cases, those of intermittent fever, and in which he found the malarial organism or plasmodium. They all had a striking number of features in common, conforming much more nearly to the classical description of an attack of ague than he had expected. The great majority of them were tertian, a few quotidian, a very few double quotidian. He had not yet seen a single case of quartan intermittent fever. He was surprised to note with what uniformity enlargement of the spleen was present in these cases. He had not seen one which had lasted a week, with the plasmodium in the blood, in which he could not discover the spleen by palpation. Palpation, he said, was much more reliable than percussion in determining the size of the spleen. Ninety-eight per cent. of all the cases in which the plasmodium was in the blood gave a fair history of having acquired the disease while away from New York. It must be borne in mind, however, that his cases came from that district below Seventy-Second Street, therefore he could not speak for the upper, newer end of the city. Cases which failed to show the organism turned out generally to be a variety of disease other than malarial, such as sepsis, tuberculosis, typhoid and other fevers.

Only a few cases of remittent fever were seen, mostly in hospitals and from tropical or subtropical countries, most of them terminating fatally, showing characteristic lesions of pernicious malarial disease. In two he was able to predict a fatal issue because of the amount of plasmodium found in the blood.

Then there was a group of cases of intermittent character, called continued malarial fever, etc., considered by many of malarial nature; cases of variable duration and intensity. The spleen in these cases, according to his experience, was not regularly enlarged so that it could be felt. The fever did not reach a very high point, might or might not fall to normal some time during the day. There was headache, malaise, perspiration, usually more marked in the afternoon. The cases did not react in a striking manner to quinine. Mild indigenous cases of this kind did not show the plasmodium, although it was found in a few cases which had come from abroad.

Then there was a group of diseases not malarial, but with a supposed malarial element, as typhoid fever, pneumonia, rheumatism, tuberculosis, and others, where the symptoms being of an irregular kind seemed to make it necessary to assume the existence of a malarial influence. In only one case of this kind, one of phthisis, had he found the plasmodium in the blood. Considering the rarity of malaria in New York, as shown by his statistics, it did not seem probable that typhoid fever, etc., should often be complicated by this affection.

In the cases of cachexia the organism found in the blood had uniformly been of the crescentic form, in a very few cases together with the amœboid. The spleen could always be made out by palpation; there was always a history of the disease having been acquired away from New York; the crescentic bodies persisted in the blood in spite of quinine. These cases resembled one another very closely, and differed from other forms of cachexia in which the organisms were not found in the blood except in one group in children. In this exceptional group in children the condition would be called by some marasmus, by others scrofula, but the organism was absent, although the spleen as well as the liver was enlarged.

The final class included the neuralgias, malaise, headaches, etc., of considerable periodicity, in which benefit might be obtained from quinine, but more often from Warburg's tincture. He had never found the malarial organism in the blood in these cases except where the symptoms were distinctly of intermittent character. There were several reasons for believing them not to be cases of malaria, among them being that they existed in non-malarial as well as in malarial places, that the spleen was not uniformly enlarged, that the malarial organism was absent, that the periodicity was due to another cause it seemed than that of malaria, in which the development of the germ was of forty hours' duration; then they responded best, usually, to Warburg's tincture, which was not a simple remedy as was quinine.

All these facts pointed to the following indications: 1. That the diseases commonly called malarial in New York City might safely be divided into two groups; *a*, malaria due to a micro-organism which caused ague wherever it existed; *b*, the non-malarial in the sense that they depended upon some other cause. 2. That of the malarial cases it could be said they showed more marked uniformity in symptoms in different cases than was generally believed, and that enlargement of the spleen in particular was present with greater constancy than was commonly supposed. 3. That in the part of the city over which his observations had extended the malarial

poison was indigenous either to a very slight degree or not at all.

Pathology.—Dr. H. M. Biggs being asked to speak of the pathology, said that so far as his post mortem experience had extended it accorded with Dr. James's clinical experience. It had been unusual for him to find well-marked post-mortem evidence of malarial poisoning in patients belonging to New York. Some time ago he had had occasion to look over the histories of four hundred and fifty cases of malarial fever in Bellevue Hospital, and of this number only four had died. One of the four was a case of pernicious malarial fever from Panama. In one death was ascribed to alcoholism, in one to tuberculosis, the fourth could not be traced. He believed the milder grades of malarial fever did not leave lesions post-mortem; reference being made to cases in which death was due to some other cause. As to the plasmodium, he had found nothing which resembled it in the blood of persons who had not had malaria.

Dr. J. M. Byron also spoke of the pathology, limiting his remarks to malaria as it existed in Panama and Egypt, where it was most typical. He said about the only change post-mortem was enlargement of the spleen, and this might be present in other diseases. As to the plasmodium of malaria, he quoted European observers who had not found it to be constant in cases evidently malarial, and he thought entire reliance could not be placed upon it in diagnosis.

The Clinical Aspect.—Dr. A. Jacobi said it had been stated that malaria was due directly to the plasmodium in the blood, and that the severe mental symptoms were caused by its great accumulation in the small cerebral vessels, and not indirectly to a ptomaïne or poison produced by it. If this were true, malaria was different from other infectious diseases, as they arose from the intermediate action of a ptomaïne or poison.

Regarding the clinical aspect of malaria in children in New York City, he said there was not much malaria in the city. There had been a good deal of it in certain localities at different times where improvements were being made, but where drainage was established and the soil left undisturbed, or where it was disturbed only a short time, malaria did not exist to any noticeable extent. It seemed the bacteria did not penetrate soil which had not been dug up. As showing the scarcity of the disease, he said he had not seen a case of malaria the last four or five months.

But what was the cause of remittent types of fever? Might not different germs produce types of malarial fever, as they might produce types of diphtheria? For his own part, he believed that diphtheria was the result of a toxine which might be produced by the staphylococcus or the streptococcus, or of the Klebs-Loeffler bacillus. Might not one form of malaria be produced by the plasmodium direct, while others resulted from a toxine? But he thought we were too much inclined to make a diagnosis of malaria when we did not know how to distinguish between disease and disease. Dr. James having shown that malaria did not exist in New York City, would make physicians somewhat shaky hereafter in such a diagnosis. Catarrhal fever was often mistaken for malaria. He described it as a fever with afternoon exacerbations, lasting about a week, beginning not infrequently with a chill or two, followed by perspiration, terminating by lysis; the mucous membranes might be affected, manifested by cough, disturbance of digestion, diarrhœa.

The Value of Examination of the Blood.—Dr. A. B. Ball presented, in writing, some observations on the value of blood examination, and on the frequency of malaria on Manhattan Island. Examination of the blood by an expert was of invaluable assistance in making a differential diagnosis between malarial fever and a great variety of other febrile disturbances simulating it. In typhoid fever one often suspected the addition of a malarial element from the peculiar course of the disease, yet during the past three years he had found the plasmodium in the blood of but one such case, and in that one there was subsequent unmistakable evidence of malarial infection.

Masked Ague.—In so-called masked ague he thought it was doubtful how far reliance could be placed on the absence of the plasmodium, and he asked if this affection might not be secondary to, rather than the direct result of, the plasmodium—somewhat analogous to periostitis, etc., following typhoid fever, manifesting themselves after the germ had disappeared from the body. But that so called masked ague was as common in the city as the frequent administration of quinine would indicate, he did not believe for a moment. Typical intermittent fever was very rare here.

The Term Malaria Inappropriate.—Dr. William H. Thomson mentioned a case of ulcerative endocarditis, one of gall-stones, and one of pernicious anæmia, which for a time could hardly be differentiated from malarial fever. They were only illustrative of a large class. He said the term malaria was inappropriate, because it meant bad air, while in fact the cause of the trouble was not bad air, but bad things—things which might produce their action by inhalation or by being taken in with the water. But we were only on the threshold of the subject, for, speaking clinically, what man present could deny that we had in New York cases characterized by chills, fever, sweating, complete remission, but differing from typical malaria in the irregularity of their course? Like malaria, they produced anæmia, headache, neuralgic affections. Were we any better off in calling them catarrhal fever, as suggested by Dr. Jacobi, for some cases? If catarrhal fever meant a fever which affected mucous membranes, it was very difficult to say what fever would not? Typhoid fever would be poorly distinguished if it were called a catarrhal fever, yet it certainly affected the mucous membrane of the intestine. We could not say that a certain class of cases commonly spoken of as malarial, and for which malarial treatment was administered, were not really malarial simply because a specific organism had not been found connected with them. When it was shown that ague was a particular form of fever with a specific cause, a great step had been taken, but might there not be other forms of this intermittent disease connected with the plasmodium or other germ? His conclusion was that typical ague was very rare in New York, although it did sometimes occur, but that a similar disease existed here very extensively, especially where streets were turned up. He thought the term malaria should be limited to the cases in which the plasmodium was present.

Four Types of Fever.—Dr. Francis Delafield said he had been in the habit of dividing the cases of fever as a disease which came under his observation into four classes: 1. Patients who had distinct paroxysms of intermittent fever. These were certainly much less numerous in New York City now than they were ten or fifteen years ago, but they were still to be seen. 2. Patients who suffered from paroxysms of fever not preceded by chill, not necessarily followed by sweating, the temperature often quite high, 104° F. or even 107° F., paroxysms coming on at regular intervals, every day, second or third day, and so on. They were not uncommon. 3. Patients who suffered from a continuous fever, lasting usually about two weeks, not often less, not often much longer; the febrile movement well marked, 103° F. to 104° F. when at its height, which was usually in the afternoon; there was usually a great deal of headache, more or less perspiration. There were cases of this kind which it seemed impossible to distinguish from typhoid fever. The first two sets of cases were benefited by the same remedies which were used for ordinary intermittent paroxysms—quinine, Warburg's tincture, arsenic. But the third class never seemed benefited by such remedies; the fever seemed to run its own course and stop when it got ready. 4. The fourth set of patients were to him the most interesting of all because the most numerous. They suffered from an irregular fever, coming and going, seldom lasting

an entire twenty-four hours, but lasting some hours out of each twenty-four; the temperature never very high, 99.5° F. to 101° F. The patients every week or three weeks have fever every day, or every other day, or skip a couple of days; it could not be put down in any regular order. The attack might last a week, a month, or even six months. The patient might have an attack a number of winters in succession. Such patients were private, did not enter hospitals, were not sick enough to be in bed, but were very miserable. The fever was not symptomatic of any disease, but was the disease itself, and when it went away the patients were well. Such patients behaved very capriciously to remedies. Some responded to quinine, others did not, some to arsenic, others not. The only thing which would with certainty stop the fever, for a time at least, was to send them away from New York, but it might return when they came back.

While the discovery of a micro organism as the cause of intermittent fever was very interesting, and made our knowledge much more definite, yet we as practitioners should recognize these other fevers, which, as fevers, not as catarrhs or catarrhal fever, or anything else, made people sick, and the point of practical importance was to find some way to cure the fever. We went on trying to manage these cases with the idea that they were malarial fever, but we did not know whether they were or were not, and some improved, while some did not, under the use of the anti-malarial drugs. We should find a better way of treating such patients, for while they did not die, they suffered a great deal.

Malaria in Children.—Dr. L. Emmet Holt in speaking on this topic said he had been surprised to find how many cases of broncho pneumonia, the first two years of life, gave distinctly a remittent temperature, and which he once thought might be due to malarial infection, but now was convinced was not, and did not respond to quinine. He used to see, when connected with a West Side dispensary, a good many cases of malarial fever in children coming from along the Hudson River and canal boats, and remarked on the uniformity of enlargement of the spleen shown by palpation, not by percussion. In doubtful cases, where the spleen was enlarged and there was prompt response to quinine, the evidence was strongly presumptive of malaria. Few cases originated in New York, according to his experience.

Dr. Simon Baruch quoted from a paper which he had written some years ago, taking the ground that malarial fever was rare in New York, much rarer than would be indicated by the treatment and reports to the Board of Health. This view has been confirmed to-night.

Dr. James, in closing the discussion, impressed the importance of not confounding typical intermittent fever, in which the plasmodium was found in the blood, and which gave a clear clinical history and showed enlargement of the spleen, with other forms of fever, whether the latter might or might not yet be proved due to some specific germ.

Proposed Air-Garden over a Reservoir.—The Academy endorsed resolutions from the Section on Public Health and Hygiene, opposing the erection of an air garden over the reservoir at Forty-second Street and Fifth Avenue.

Public Free Baths.—The resolution adopted by the Northwestern Medical and Surgical Society, recommending to the city authorities the establishing of practically free baths, on the plan advised by Dr. Baruch, and requesting the endorsement by the Academy, was laid on the table until the next meeting, in order that Dr. Baruch might have opportunity to explain it to the members who had not heard his paper on the subject, read elsewhere.

Tuberculosis in Cattle.—Several cases of supposed tuberculosis have appeared among the cattle of Chester County, Pa. Steps are being taken to prevent the spread of the disease.

SECTION ON SURGERY.

Stated Meeting, March 9, 1891.

William T. Bull, M.D., Chairman.

Thiersch's Skin-Grafting; a Case.—Dr. Robert Abbe presented a woman who had sustained a burn involving over two-thirds of the surface of the arm, forearm, and hand, from about the insertion of the deltoid down. A few weeks after the accident granulations had sprung up, and flaps were transplanted from the thigh, according to Thiersch's method, the procedure being carried out at the request of Dr. Abbe by Dr. Dunham. The largest grafts were about half the size of a postal card. All the grafts united at once, leaving the surface smooth and supple.

Report of Three Cases of Nephrectomy.—Dr. F. Kammerer read the history of the cases (see p. 368).

Dr. Willy Meyer thought that where purulent urine was coming from one ureter, and we were unable to determine by the cystoscope whether the urine coming from the other were clear or not clear, we would not be justified in removing the one kidney until by tying the ureter or by other means we had been first enabled to decide whether the kidney on the other side was healthy. He also spoke of prolapsus of the mouth of one ureter as indicative of an irritative process in the pelvis of the kidney.

Dr. Kammerer did not think the mere presence of turbulent urine from one ureter necessarily contraindicated extirpation of the other kidney for disease.

Tube Lost in the Œsophagus.—Dr. R. F. Weir reported three cases, the first being a case in which a tube was lost in the œsophagus. The patient had a malignant stricture, situated fifteen inches from the teeth, was suffering from great difficulty in deglutition, which Dr. Weir was able to relieve greatly by the introduction of one of Simon's tubes. He first introduced a rigid whalebone staff, with a flexible end, through the strictured portion, and over this guide passed down the tube. When it had reached the strictured portion some force was required, which he exerted by means of Mixter's method, that is, he introduced a stiffer rod, one end of which composed a hollow cylinder fitting into the tube which was to remain permanently in place, and passing over the whalebone guide. It was afterward removed, as was also the whalebone guide, leaving the tube in the strictured portion, with a string attached by which it could be removed when desired. In one of his cases, and in one or more others on record, this string, which was fastened to the ear, had been chewed off, and to avoid repetition of the accident he now fastens it to a tooth. In his case the tube, after the string had been chewed off and swallowed, was brought up by aid of an emetic.

Spleen Removed after Gunshot Wound.—Dr. Weir next presented a spleen which he had removed in a case of gunshot wound of the abdomen. The bullet had entered just below the left nipple and had come out in the lumbar region on the other side, about one inch below the twelfth rib. The peritoneal cavity was full of blood, which was found to be coming from the vessels of the spleen. An attempt was made to tie these, but they were too friable, consequently the organ was removed. The small intestine contained four wounds, was fastened in the abdominal opening, with the idea of treating the intestinal fistula afterward if the patient lived. As was expected, he soon died.

Nephrectomy for Primary Sarcoma.—Dr. Weir presented a third specimen, consisting of a kidney—removed on Monday last, for cystic sarcoma—the size of one's head. It was taken out by the transperitoneal method, lifting the edges of the peritoneum to the abdominal wound, establishing drainage posteriorly, taking the tumor out through the anterior wound and closing the peritoneum and abdominal incision. Thus the fluid was kept postperitoneal. One-half the kidney appeared healthy; the fatty envelop was condensed and showed inflamma

tory or possibly neoplastic change, which rendered the operation a little more difficult.

On the Danger of Administering Chloroform in the Presence of an Open Flame.—Dr. R. W. Amidon read a paper on this subject. It had been suggested to him by an experience which he had had when assisting at an operation where pure chloroform was administered in a room in which several gas-burners were lighted. After some minutes he began to suffer from a pungent, irritating gas, which caused great irritation of the respiratory tract, with severe coughing. The dry, irritating cough continued about twelve hours. Another person in the room suffered in the same way. In some published cases the same cause had produced further symptoms of nausea and vomiting. On investigation he had learned that the gas which produced this irritation was phosgene, produced by the decomposition of chloroform in the presence of a flame. While no cases had been recorded in which death could be traced directly to this source, the question suggested itself whether it may not have been the exciting cause of a fatal broncho-pneumonia in some cases after operations. It was disagreeable enough to the operator and assistants, and might prove a serious complication to the patient's malady. The danger was greater where much chloroform was used, the room low and small, and an open gas jet or kerosene stove was burning. The irritating gas did not develop in the presence of the incandescent light. Its formula was $COCl_2$.

Dr. Weir said he had never had cough or respiratory difficulty in a room where chloroform was being administered. Dr. Abbé had had one experience like that described by the author, it being in Dr. Lange's operating-room, where a gas stove was burning, and Dr. Lange said that not infrequently those not accustomed to it were troubled with cough when witnessing his operations. Dr. Willy Meyer had had one personal experience; Dr Kammerer had had none; Dr. van Arsdale had operated and assisted at operations often where chloroform was administered by gas-light, without experiencing any inconvenience, a fact which he was disposed to attribute to the kind of inhaler used, one which prevented admixture of atmosphere; he had known another person who had witnessed the "chloroform fog" two or three times. Dr. Bull had had one striking experience while operating in a country house, using chloroform, two gas jets burning, all present including himself, being nearly overcome until the door was opened. He said it spoke somewhat against chloroform, which was now being urged in abdominal surgery, since most of these cases demanded immediate operation wherever the patient might happen to be. Dr. Agramonte had had no such experience, nor had he heard it mentioned in a recent meeting of obstetricians where chloroform administration was discussed, although this anæsthetic was often used when delivery was about to be completed.

Antiseptic Forceps.—Dr. Van Arsdale presented a wedge-shaped forceps, which possessed the advantage over the ordinary smooth antiseptic kind that, owing to their shape when the blades were compressed, the fingers would not slip.

Demonstration of a new Cystoscope.—Dr. Willy Meyer demonstrated the working of the French cystoscope, which was designed by Boisseau du Rocher, of Paris. The first report regarding it was made to the Académie des Sciences in 1885, but the instrument was not used by others until last year, when B. du Rocher described it at length in an article which appeared in the *Annales des Maladies des Organes Genito-urinaires*, February, 1890. The advantages which this instrument possessed over Nitzer's were more than counterbalanced by the disadvantages.

Medical Legislators.—In the first Japanese Parliament three members of the House of Peers and four of the House of Commons are physicians.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, February 26, 1891.

Egbert H. Grandin, M.D., Chairman.

Colloid Sarcoma Weighing Thirty Pounds.—Dr. Florian Krug presented a colloid sarcoma weighing about thirty pounds which he had recently removed from a woman by laparotomy. It was of interest because of its very large size and rapid growth. The patient was brought to his office January 30th, and gave the following history: aged thirty-one, mother of five children, the last one born two years ago, nursed until May, 1890; had had no period since. Since last summer she had noticed an increase in size, both she and her physician supposed she was pregnant. When she came to his office she consisted of skin and bones and of a large abdominal tumor, the waist measuring 44.5 inches. There was no fluctuation; tumor of the uterus could readily be excluded. An exact diagnosis could not be made, although it was supposed the growth was malignant. The pulse was rapid, intermittent, and weak, but, with the consent of the patient and husband, he operated February 6th. Although the incision extended from near the symphisis to near the ensiform cartilage, it was necessary to take several quarts of the colloid material out of the tumor before it could be extracted. Adhesions were tied off. The operation, performed as hastily as possible, occupied thirty-five minutes. He left, as the best means of stimulating the patient, a solution of salt in sterilized water, 6 to 1,000, in the abdominal cavity for absorption. Other stimulants were employed. Notwithstanding death was soon expected, yet the patient improved and did very well for four days, then a change took place, and she died on the sixth day from, as the autopsy showed, a fresh pericarditis. There were signs of an old endocarditis.

Dr. Andrew F. Currier said he could sympathize with Dr. Krug, since he had very recently removed a carcinomatous tumor weighing forty pounds from the abdomen of a woman where it had also grown very rapidly; he left salt water in the abdominal cavity, and injected digitalis and strychnine, which had been recommended by Dr. Wood as most desirable stimulants in cases of heart shock, but the patient never rallied. If the tumor were not malignant, he thought it might lessen shock to drive some of the blood from the tumor back into the general circulation by the Esmarch bandage, if this could be applied. These patients, however, were almost sure to die under the operation, and he doubted the advisability of interfering.

Old Diseases Renewed after Operations.—Dr. G. M. Edebohls asked Dr. Krug whether his patient had ever suffered from rheumatism, and said that he had sometimes found patients come back after operations complaining of some trouble which physicians were likely to treat lightly. On further study he had found that old affections, such as rheumatism, rheumatic endocarditis or pericarditis, etc., were liable to recur after laparotomies or other operations, and therefore patients should be kept under observation for some weeks or months after receiving surgical treatment.

Dr. R. A. Murray, having witnessed the operation performed by Dr. Krug, remarked upon the large adhesions, the obstacle to ligating the ovarian and uterine arteries, the objections to the use of Esmarch's bandage in this case, the advantages of Trendelenburg's position, whereby the blood was kept more in the brain and prevented so great shock; and he, with the other speakers, disagreed with Dr. Currier as to letting these patients with enormous tumors go without an operation because it was attended by great risk.

New (?) Method of Fixing the Uterus.—Dr. A. F. Currier related a case of obstinate retroflexion in which he performed laparotomy, removed the diseased appendages on one side, and then fixed the uterus by a method which to him was new, although a modification of the

one proposed by Olshausen. He passed silver wires through the uterus, one on each side, below the opening of the Fallopian tube, then through the abdominal wall, emerging from the skin about three fourths of an inch external to the abdominal wound. He expressed preference for silver wire on account of its remaining aseptic.

The Chairman said the operation was not new, since he and others had performed it, and he agreed with Dr. Krug and Dr. Edebohls, who had said that silk-worm gut was as little likely to take on sepsis as silver wire and was preferable in other respects.

The Atmospheric Tractor—A Substitute for the Forceps.—Dr. P. McCahey, of Philadelphia, by invitation, was to have demonstrated on the manikin the use of the atmospheric tractor, but the manikin at hand was not suitable for this purpose, and he therefore showed the instrument, a kind of cup with handle made of thick, soft rubber, showed its tractile power on the head of the dead baby, spoke of its uses, and compared it with the forceps. The tractor which he exhibited covered an area of about five square inches, and exerted a force, when applied to a wet surface like the head of the newly born, of from twenty-five to thirty-two pounds, or over one-third of the atmospheric pressure, which is fifteen pounds to the square inch. He claimed that the instrument could be applied with facility, furnished a sufficient amount of force to extract the child, was positively harmless, and could be used with perfect safety in both normal and abnormal labors. In normal labors it was employed to shorten suffering. Of course the os must be dilated to a size as great or greater than that of the tractor. The speaker had employed the instrument in about twelve cases, and had delivered in from five to twenty-five minutes, where nature would probably have required two hours or more.

With the tractor one could direct the head through the canal as might be desired, and one of its chief advantages was in prevention of rupture of the perineum. All objections to the instrument had been offered on theoretical grounds, and had not held in practice.

None of the gentlemen present who discussed the use of the tractor had had experience with it, but all seemed pretty generally of the opinion that it would be useful after the head had entered the pelvic canal, and in preventing rupture of the perineum, but that it could not be applied at an earlier stage, especially in primiparæ, or, if it could, that it would not exert sufficient force to take the place of the forceps where this instrument had generally been indicated.

In closing the discussion Dr. McCahey extolled the tractor as a means of lessening the pain of labor, claimed that the objections offered during the evening did not hold in practice, that the tractor could be applied at any stage when the os was sufficiently dilated, and while not asserting that it could entirely take the place of the forceps, yet expressed the belief that it would do so in many cases where these instruments had been used in the past, and not infrequently had caused injury to child or mother.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, February 16, 1891.

Dr. S. B. W. McLeod, President, in the Chair.

Address of the Retiring President.—Dr. George T. Harrison, the outgoing President, read some remarks upon the advantage to be gained from a study of medical writings of the past. The tendency at present was to neglect the past and to adopt nothing but what bore the stamp of modern. Everything written even only a few years ago, nay, a few months ago, was thrust aside with the sententious expression that it was antiquated. History, as it related to medicine, would prove a corrective of the proneness of the young mind to underestimate the achievements of the past, and to pay undue attention to the new, or what appeared to be new.

Address of the President-Elect.—Dr. McLeod expressed appreciation of the honor conferred upon him; mentioned the objects of these meetings, one of which was to cultivate closer relations with the State and National Associations; incidentally remarked that no political action should restrict our use of medicines because brought from other lands; quoted Peaslee on the advantage of belonging to a medical society and of attending the meetings.

Synopsis of a Letter on the Koch Discovery.—The letter, which was read in abstract, was from Dr. Henry B. Douglas, now of Berlin. The reaction after the injection of the lymph, the letter stated, was in proportion to the amount of tubercular tissues present; that the reason for the reaction ceasing to take place was supposed to be that all the tubercular tissue had been broken down; and one author was of the opinion that when, after an interval, reaction again followed the injections it indicated reinfection elsewhere from previous necrosed broken down tubercular tissue. In tuberculosis of the joints the same reaction took place after the injections, and the sequestrum should then be removed by the surgeon. Local reaction in tubercular meningitis was such as to give rise to dangerous symptoms and contraindicated treatment in that class of cases. While there was no doubt, the author thought, but what the injections would kill all tubercular tissue in the lungs, yet this was only part of the cure. This tissue must be removed, and he suggested that here was a good opportunity for pulmonary surgery.

Perforation of the Membrana Tympani. Dr. Von Beverhout Thompson read the paper. Perforation of the membrana tympani was usually due to chronic suppurative ear disease. It took place in nearly all of this class of cases, and was present in one-third of all cases appearing at the several institutions for disease of the ear in the city during a number of years past. Adding to this number, due to suppurative inflammation of the ear, those which arose from injuries, etc., the percentage of all cases of ear disease which went to the institutions and had perforation would rise to thirty-five. The author here referred to the anatomy and appearance of the membrane, and its use. Besides carrying atmospheric vibrations produced by sound to the ossicles, it also served as a protector for the middle ear. Going on to speak of causes of perforation, he divided the cases under three heads—the congenital, the mechanical, and the diseased. Congenital cases had been spoken of by several authors, but evidently were very rare. Among mechanical causes were the introduction of sticks, small buttons, etc., blows on the head, diving, violent sneezing, cannonading, etc. But the most frequent cause was disease, the pus and mucus in the middle ear being unable to escape through the Eustachian tube, finding their way out through the drum-membrane. The most persistent perforations were due to fevers, especially measles and scarlet fever. Nasal catarrh or "colds" had perforation of the membrani tympani as one consequence. The author related, briefly, three cases in children, in which he thought inflammation and perforation were sympathetic, due to dental irritation. The author was disposed to attach greater importance to a perfect drum-membrane than some had taught. Given a number of cases of perforation, there could be no question but what a certain, though small, proportion of the persons would die from inflammation of the brain or its membranes, of pyæmia, etc. While the power of hearing in cases of perforation was not destroyed, yet it was diminished; a watch which would be heard six feet by the normal ear would probably be heard at one or two feet with the affected ear.

In discussing the treatment the author emphasized the importance of an early recognition of the causes of perforation, as by proper treatment of this the aural lesion could frequently be prevented. In measles, scarlet fever, and throat troubles from other causes, one could not be too early in applying proper remedies to prevent extension of the inflammation up the Eustachian tube. To tell a patient who complained of pain in the ear to ap-

ply a poultice and wait for something to burst would be to court the very result which it was most desirable to obviate. The ear should be syringed thoroughly with warm water, not using much force, then some solution could be injected or applied with a probe and cotton, and repeated every two or three hours until pain was relieved. Dr. Agnew, he said, advised, where pain had lasted over night, application of a leech to the tragus, and if relief were not obtained in three or four hours, incise the drum-head. Often, however, patients would object to paracentesis, yet it should be performed when pain could not be controlled. After incision, inflate the ear through the Eustachian tube, and give anodynes freely. Before incision, however, they should not be given, as they masked the process. As long as there was tendency for matter to become pent up, no harm would come from repeated incision of the membrane. Where perforation had taken place spontaneously from disease, perfect cleanliness was the chief indication obtained from injections. With chronic inflammatory process an astringent was called for after the cleansing, as of sulphate of zinc, nitrate of silver, etc. Reference was also made to the dry treatment by powders.

An artificial drum improved hearing and protected the middle ear from changes of temperature, etc. When there was destruction of the ossicles there could be no benefit from its use, unless as a protection to the cavity. After describing other artificial drums the author exhibited one improved by himself, which he had found the most useful, consisting of a small silver wire wound around an ear speculum so as to form a ring to fit the ear, the two ends then twisted together to project from the ear, and over the ring a thin piece of gold-beater's skin stretched, and tied around the twisted ends by a silk thread. The skin was then shellaced to prevent softening by fluids. The artificial drum was taken out at night.

Perforation a Broad Subject.—Dr. J. H. Claiborne, Jr., was not surprised on listening to the reading of the paper to find that in treating of perforation of the drum-membrane the author had encountered a broad subject; that it had resolved itself largely into a consideration of suppurative otitis media. As to the frequency of perforations, he felt sure more than one-third of the cases seen by him were of chronic purulent otitis media, which meant practically perforation. As to mechanical causes, a very unusual one had come under his observation, namely, loud shouting; measles and scarlet fever were the common causes. He had never seen a case due to diphtheria. As to dental irritation setting up sympathetic inflammation of the ear and perforation, he doubted whether it ever took place; there probably was some other cause which had been overlooked. He agreed with the statement that the presence of an air bubble was a good but not positive diagnostic sign of perforation. He did not use the probe with cotton; it was too dangerous. It were better to leave on a little pus after the injection and apply the medicine over it rather than take the chance of doing injury in removing it with the probe and cotton. As to paracentesis he probably stood alone in opposing it, especially repeated incision. He had had reasonably good success in treating acute inflammation of the middle ear without it. He was strongly in favor of the Eustachian catheter, although it was not much used here and abroad. With the aid of cocaine it could be employed without difficulty. In purulent inflammation with perforation he had found a four per cent. solution of carbolic acid the best application, using it after washing out with a solution of borax or salt. Do not entirely fill the ear with it. As to powders, the majority of aural surgeons now advised great caution in their use. The best artificial drum which he had employed was a small disk of wet cotton. A wire projecting from a drum would be likely to do injury.

Dr. H. S. Oppenheimer said that a common cause of perforation of the drum-head from within was polypoid growths, which had not been mentioned in the paper. Where perforation was likely to take place he much preferred it should be by incision, where it would be even and likely to heal—usually it healed too readily—than by suppuration, where ragged edges would be likely to remain and heal with difficulty. He chose the lower posterior quadrant of the membrane for making the incision. The Eustachian catheter could hardly be used in children, who were often the subjects calling for treatment. As to diminution of the hearing power from perforation, he thought it was not so great as had generally been supposed. He had also found cotton the best artificial drum, and that others with a stem were likely to do harm.

Dr. Thompson, in closing the discussion, said it had been suggested to wrap the projecting wire with cotton to prevent harm.

Correspondence.

THE DISPENSARY QUESTION.

To the Editor of the Medical Record.

Sir: Will you permit me to say a word in behalf of that much-abused institution the dispensary?

First, as to the oft-repeated assertion that it is a pauperizing agency. That it gives medicine and advice to many individuals who could, by an effort, contrive to pay a physician, is true; but that these individuals are thereby pauperized I cannot think. For many thousands of families in New York, life is a hard struggle for the maintenance of respectability. To keep themselves above the tenement-house class costs every dollar that they can earn. In time of sickness, with income reduced and expenses increased, it is almost inevitable that they descend to the level of the tenement-house population; that they lose the respect of their neighbors, to say nothing of their own self-respect, which in all probability is founded, not on abstract philosophy, but on things temporal and physical, and that their children be exposed to the evils, physical and moral, of life in a densely populated, dirty neighborhood. Any institution which helps them to escape this evil, is, it seems to me, doing a most commendable work. The patients at a dispensary are not paupers, any more than the visitors to the libraries, parks, and museums. The value of the public works of Boston, if divided among the families of that city, would amount to about four thousand dollars each, that is, each family may be said to have the use, gratis, of four thousand dollars worth of property. Yet families which have contributed little or nothing toward the erection of these works are not, on that account, considered paupers. Neither should a man who, in time of sickness avails himself of what is freely offered by some of our public-spirited citizens, be called a pauper.

But this, I take it, is a mere side issue. The real cause of all this agitation is the fact that the dispensaries are making it hard for some of the doctors to make a living. Therefore they should be abolished, or their activities restricted! That any self respecting physician should put forward such an argument as this is to me amazing. It is constantly happening that special skill and special kinds of property lose their money value. When petroleum was discovered, the whaler's occupation was gone. Every new machine throws hand-workers out of employment. Nevertheless, petroleum and machinery are good things. Mankind are the better for their existence. So are the hospital and the dispensary good things. Our great cities are vastly better for their existence. Were it possible for every man, woman, and child in New York to secure medical attendance free, to be relieved from the burden of sickness, the community would be by just so much the better off.

As to the physician whose occupation has been taken from him, he must, at the worst, do as the whaler and the

hand-worker have done, find some other occupation. His plight is unfortunate, but it is temporary. The supply of physicians, as of workers of every other class, will adjust itself to the demand. The dispensary is an almost unqualified good, and has, I hope, come to stay. To demand, in a spirit of narrow trades-unionism, that its activities be curtailed, is like demanding that the sun be darkened that the candle-makers may be prosperous; it is a position to be expected, perhaps, from a tradesman, but unworthy a physician and a gentleman. F. R.

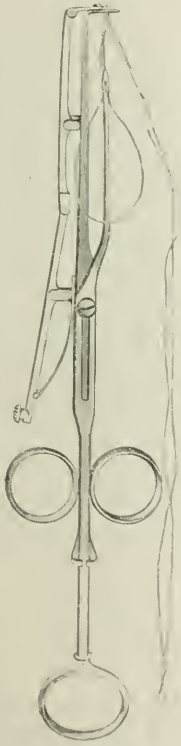
New Instruments.

NEW STAPHYLORRHAPHY-NEEDLE.

By HERMAN MYNTER, M.D,

PROFESSOR OF SURGERY, NIAGARA UNIVERSITY, BUFFALO, N. Y.

DIFFERENT instruments have been invented in order to apply the sutures with greater ease on the soft palate in staphylorrhaphy. Goodwillie's needle is probably one of the best, and not least on account of its simplicity. Nevertheless, I have met with considerable difficulty in using it. Considerable force is necessary in order to force it through the tissue, and the soft palate has to be hooked quite firmly to steady it. The process is quite painful, even under cocaine, and prolonged more than desirable. The instrument I here offer to the profession is a modification of an old instrument shown to me by Dr. John Cronyn, of Buffalo, and invented in 1836 by Dr. W. R. Beaumont, then one of the surgeons to St. Bartholomew's Hospital, London, afterward Professor of Surgery in the University of Toronto. His instrument resembles a pair of scissors, one point of which is curved and has an eye. By closing it the curved point perforates an eye in the other point, on the other side of which the thread is caught by a simple arrangement. It works from side to side, and was used at first in vesico-vaginal fistula, later in staphylorrhaphy; but for the latter operation its construction is faulty, as it acts from side to side. The instrument I here offer acts from before backward. The needle perforates one side of the palate, the double thread is caught behind, and withdrawing the needle we have one loop. Repeating the process on the other side, another loop is secured, which is then passed through the first loop, which is then withdrawn. By aid of the loop left a silver wire or silkworm gut may be quickly applied. The instrument has the advantage of acting quickly and almost painlessly, and of making it unnecessary to use a hook on the palate while the sutures are inserted. It may be procured from Mr. Henry Hermann, of No. 7, W. Huron Street, Buffalo, N. Y., who has carried my idea into perfection.



The Mississippi Valley Medical Association will hold its seventeenth annual session at St. Louis, Mo., Wednesday, Thursday, and Friday, October 14, 15 and 16, 1891.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 15, 1891, to March 21 1891.

WINNE, CHARLES K., Captain and Assistant Surgeon. To be Major and Surgeon, February 22, 1891.

FRYER, BLENCOE E., Lieutenant-Colonel and Assistant Medical Purveyor. Retired, February 24, 1891.

GREENLEAF, CHARLES R., Major. To be Lieutenant-Colonel and Assistant Medical Purveyor, February 24, 1891.

WILCOX, TIMOTHY E., Captain and Assistant Surgeon. To be Major and Surgeon, February 24, 1891.

AINSWORTH, FREDERICK C., Captain and Assistant Surgeon. To be Major and Surgeon, February 27, 1891.

HAVARD, VALERY, Captain and Assistant Surgeon. To be Major and Surgeon, February 27, 1891.

VOLLUM, EDWARD P., Colonel and Chief Medical Purveyor; BACHE, DALLAS, Lieutenant-Colonel and Surgeon; GIRARD, ALFRED C., Major and Surgeon; and GANDY, CHARLES M., Captain and Assistant Surgeon. By direction of the Secretary of War, a board of medical officers, to consist of the above members, is constituted, to meet in New York City on March 16, 1891, or as soon thereafter as practicable, for the examination of candidates for admission into the Medical Corps of the Army, and such other business as the Surgeon-General may desire to bring before it. S. O. 52, par. 18, A. G. O., Washington, D. C., March 7, 1891.

RAYMOND, HENRY I., Captain and Assistant Surgeon. By direction of the Acting Secretary of War, is relieved from duty at Newport Barracks, Ky., and assigned to duty at Fort Thomas, Ky., reporting in person to the commanding officer of Fort Thomas, and by letter to the Commanding General, Division of the Atlantic. S. O. 54, par. 18, A. G. O., Washington, D. C., March 10, 1891.

FINLEY, JAMES A., Captain and Assistant Surgeon. Having been found, by an army retiring board, incapacitated for active service on account of disability which is not the result of any incident of service, is, by direction of the President, wholly retired from the service this date, under the provisions of Sections 1252 and 1275, Revised Statutes, and his name will henceforward be omitted from the army register. S. O. 54, par. 2, A. G. O., Washington, D. C., March 10, 1891.

SHANNON, WILLIAM C., Captain and Assistant Surgeon, now on duty at Fort Apache, Ariz. By direction of the Acting Secretary of War, will repair to this city, and report in person to the Adjutant-General of the Army for further orders. S. O. 55, par. 5, A. G. O., Washington, D. C., March 11, 1891.

BIRMINGHAM, HENRY P., Captain and Assistant Surgeon. Granted leave of absence for one month with permission to apply for an extension of one month, to take effect upon arrival at Boise Barracks, of First Lieutenant Robert R. Ball, Assistant Surgeon. S. O. 39, par. 2, Department of the Columbia, March 13, 1891.

MIDDLETON, PASSMORE, Major and Surgeon. By direction of the Acting Secretary of War, is relieved from duty at St. Francis Barracks, Fla., and will proceed to Newport Barracks, Ky., and await further orders. The travel enjoined is necessary for the public service. S. O. 62, par. 8, A. G. O., Washington, D. C., March 19, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 21, 1891.

KITE, G. W., Passed Assistant Surgeon. Detached from the New York Hospital, and ordered to the Lancaster.

NORTH, J. H., JR., Assistant Surgeon. Detached from the Lancaster and await orders.

SMITH, G. T., Assistant Surgeon. Detached from the Independence, and ordered to the Mohican.

LUNG, GEORGE A., Assistant Surgeon. Detached from the Mohican, and ordered to Washington, D. C., in charge of insane patients.

CLEBORNE, C. J., Medical Director. Detached from Naval Hospital, Norfolk, Va., and ordered to the Naval Hospital, Chelsea, Mass.

PENROSE, T. N., Medical Inspector. Ordered in charge of Naval Hospital, Norfolk, Va.

STEELE, JOHN M., Passed Assistant Surgeon. Detached from Coast Survey Steamer Bache and granted three months' leave of absence.

GAINES, JAMES H., Surgeon. Placed on the retired list, March 18, 1891.

RUTH, M. L., Surgeon. Granted a month's leave from April 2d next, with permission to leave the United States.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 21, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	14	1
Scarlet fever	159	21
Cerebro-spinal meningitis	1	4
Measles	405	16
Diphtheria	92	29
Small-pox	1	1
Varicella	6	0
Pertussis	0	13
Croup	0	0
Mumps	0	0
Rötheln	0	0

Beriberi and Rice.—Dr. Takaki, of the Japanese navy, came to the conclusion, some years ago, as a result of numerous experiments, that kakke, or beriberi, was due in large measure, if not altogether, to the use of food deficient in nitrogenous and fatty matters. This theory was put to the test of actual experiment in the navy, the food of the sailors being materially changed, in accordance with Dr. Takaki's views, and the result has been that the disease has almost entirely disappeared in that service. The *Sei-I-Kwai Medical Journal* publishes a table giving all the cases of beriberi in the navy from 1878 to 1889 inclusive, in which the result of this change of diet is strikingly shown. The change was effected in 1884. Previous to that year the number of cases had ranged from 1,163 to 1,978, or from 23.12 to 40.45 per cent. of the entire force. In 1884 the number fell to 718, or 12.74 per cent. of the force, while in 1889 there were but 3 cases, or .03 per cent. of the active force. During 1890 the number of sufferers from kakke in the empire was unusually small, and this, Dr. Takaki attributes to the fact that the price of rice was very high, so that the common people were obliged to use much less of it than usual, eating in its place wheat and beans. This investigator is now studying the relation between the number of kakke patients and the quality of food consumed in the public boarding-schools throughout the empire.

The Transmission of Diphtheria from Animals to Man.—Dr. José Brusque, of Pelotas, Brazil, reports several cases in the *Bulletin Général de Thérapeutique* of December 30, 1890, in support of the view that diphtheria may be transmitted from the lower animals to man. In the first case, a farmer had skinned a horse which had died of tonsillitis, his children assisting him in the operation. A few days after this the children were attacked with diphtheria and died. They lived out in the country, and no one in the vicinity had had the disease. The second case was almost exactly similar, except that the victim was an adult. In the third case, a number of chickens belonging to a farmer had died of pip, and had been eaten by the pigs. One of the hogs became soon after attacked with a throat trouble, and in order to prevent asphyxia, the farmer performed a tracheotomy, his little child, five years of age, being present at the time. In a few days this child was seized with a throat trouble, and died without medical assistance. Shortly after her death, her older sister was brought to town to the writer, and was found to be suffering from diphtheria. This family lived twenty miles from the nearest settlement, and had seen no strangers, nor had any member of the family been to the town for a long time.

Quinine and Hæmoglobinuria.—It has often been observed, especially in Italy, that acute intermittent fever may become complicated by hæmoglobinuria, more especially after several paroxsyms have taken place, and it has been supposed by some that the occurrence of this phenomenon was due to the action of the quinine given to control the malarial attacks. Dr. Tiraboschi has, however, investigated this question very thoroughly, and comes to the conclusion that the fever, and not the quinine, is the cause of the hæmoglobinuria. He has seen cases in which this symptom appeared during the administration of quinine in moderate doses, and others in which it has disappeared while the drug was still being given in fairly large amount.

Asiatic Cholera in a Dog.—Professor Ogata, of Tokio, reports a case of cholera occurring in a dog. The dog had been vomiting and purging for some time, and was brought to Dr. Ogata's laboratory by a police-surgeon. After the death of the animal several plate cultures were made of the contents of the small intestine, from which comma bacilli were obtained in almost pure culture. Examination, under the microscope, of a thin piece of the small intestine, which had been kept in alcohol and stained with gentian violet and alkaline methyl blue, showed the presence of the comma bacilli, not only on the surface of the mucous membrane, but also within Lieberkuhn's glands.—*Sei-I-Kwai Medical Journal*, No. 106.

HEMIANOPSIA.

By HENRY D. NOYES, M.D.,

NEW YORK.

THE subject which I am to consider is a visual manifestation of intra-cranial disorder. My remarks will relate to the visual disturbance rather than to the cerebral pathology. I ask more critical attention to this symptom in the hope that light may be shed upon the intricate problems of cerebral disease. The aim is to reach greater precision in cerebral localization, by closer study of visual symptoms.

Let us briefly sketch the course of the visual tract from the retina to its ultimate destination in the brain. The peripheral percipient elements in the retina are the cones and rods, which are connected by fibres with the outer and inner granule layers and by successive fibres with the ganglion cells; from these proceed the optic nerve fibres. The number of cones and rods is estimated to be seven times as numerous as the optic nerve fibres, and the estimate of optic fibres is between four hundred and thirty-eight thousand (Salzer) and one million (Krause).[2] The optic nerve fibres lie in layers, but in the region of the macula lutea they are finer and in fewer layers, and anastomose freely. At this space the bundles into which they are collected, cannot, as elsewhere, be separately traced. The macular fibres are the most important in function, and are clustered into a triangular bundle composing about one-fourth of the nerve, which enters the papilla at its infero-temporal side. As it pursues its way through the orbital portion, it gradually approaches the axis of the nerve, which it reaches at the optic canal. At the front of the chiasm it occupies its upper and inner portion, but in the tractus it sinks to the central portion and remains there until it arrives at the brain. The semi-decussation of the optic tract in the chiasm is an accepted fact, despite the incredulity of Michel. The papillo-macular bundle is likewise divided into crossing and direct fibres which at the anterior part of the chiasm can be separately distinguished, but at its posterior part and in the tractus become inextricably mingled. The macular fibres anastomose with each other in the retina and they have additional opportunity to do this in the chiasm and the tractus. The tractus winds around the crus cerebri and terminates in two roots upon the corpora geniculata externa and interna and upon the posterior part of the optic thalamus, called the pulvinar. Fibres also go to the anterior pair of the corpora quadrigemina, but these organs are not regarded as concerned in vision, but in the activity of the pupil. The parts just referred to are called the primary visual ganglia.

In them we find innumerable ganglion cells in which fibres of the tractus lose themselves, and thereafter a new set of fibres proceeds backward through the posterior part of the internal capsule to the cortex under the name of the visual radiation, or fibres of Gratiolet or of Wernicke. Passing through the internal capsule they cross the sensitive fibres coming down from the hemisphere, are rather closely massed, and then, spreading out like a fan, rise upward, wind outside the tip of the lateral ventricl to reach their destination at the lower part of the median surface of the occipital lobe.

Varieties of Hemianopsia.—In all cases the dividing line is either horizontal or vertical, the definition not being very exactly interpreted. There may be loss of half the field in only one eye and this points out a lesion of one optic nerve in front of the chiasm. If both upper or both lower half fields are wanting, the seat of lesion will be on the lower or upper part of the chiasm, or of both optic nerves. A case very briefly reported in the *British Medical Journal* for November 22, 1890, had loss of the upper half of the field in one eye, and of the lower half in the other eye. This requires a double lesion in front of the chiasm. Total blindness of one eye combined with loss of the half or of the quarter of the field in the other is explained by a lesion of both nerves, on one side complete, on the other side incomplete. All these are peripheral lesions; and the same is true of the cases of bi-temporal and bi-nasal hemianopsia. Bi-temporal half blindness is explained by a lesion at the middle of the chiasm involving the crossing fibres from both tractus. It may be from tumor (Weir Mitchell), it may be from fracture at the base of the skull, etc.

The excessively rare condition of bi-nasal hemianopsia presupposes a lesion on both sides of the chiasm, or on the outer side of each optic nerve and impairs the direct fibres (Knapp).

We are chiefly interested in another variety of hemianopsia, viz., that which affects the same side of each field and in which the dividing line is nearly vertical. This variety, called homonymous, implies injury of the visual tract behind the chiasm. On this subject most admirable papers have been written, by Starr, 1884; by Seguin, 1886 to 1887; by Hun, 1887; and by Swanzy,[1] in which are set forth other distinctive and localizing symptoms which accompany the visual defects by which the focus of the disease may be more or less accurately determined. To these symptoms I shall only incidentally refer. My purpose is to call attention to some peculiarities in the fields of the vision which have not been generally attended to. I am indebted for much of what I offer to the last monograph by Wilbrand, an atlas of hemianopic defects, 1890, Wiesbaden.

The dividing line in hemianopsia is sometimes precisely on the vertical meridian and straight. That it is many times not on the vertical meridian and not straight has long been observed.[2] This occurs both in the peripheral, *e.g.*, bi-temporal and in the central forms. It may bend around the point of fixation upon the blind side, and thus greatly mitigate the injury inflicted on sight by sparing the whole of the macula lutea. That the boundary of the blind half may not for a considerable extent reach the vertical meridian and may be a sinuous or oblique line, or form an open angle, has also been noted. Wilbrand points out that in 77 cases of homonymous hemianopsia the dividing line was central in 29 cases. In 33 the blind portion was smaller than the seeing portion of the retinæ and to an equal extent in both eyes. In 5 cases the dividing line was in one eye central and in the other eye was pushed away from the fixing point toward

[1] Read before the New York Academy of Medicine, February 8, 1891, and illustrated by lantern slides.

[2] For these statements see Wilbrand die hemianopische Gesichtsfeld Formen, Wiesbaden, 1890.

[2] See Schweigger: Graefe's Archiv, vol. xxii., abth. iii., p. 276, 1876.

the blind side. In 10 cases the amount of displacement of the dividing line beyond the vertical meridian was unlike in the two eyes. The blind side is always either smaller in area than the seeing side, or may be equal to it. It is never greater.

Out of 32 cases of bi-temporal hemianopsia in only 9 did the boundary coincide with the vertical meridian. In 12 total blindness of one eye precluded comparison. In 20 cases the blind sides were the smaller. We cannot, at present, draw any practical deductions from these facts, and in explanation of them we have to refer to the anastomosis of the fibres from each tractus in the retinæ as well as in the optic nerves and chiasm where crossing and direct fibres lie in close relation to each other.

But a new significance attaches to this circumstance since the publication within the year of two cases of double hemianopsia, one by Forster,[1] and another by Schweigger.[2]

Forster's case was a man who at forty-four years of age had from apoplexy complete homonymous hemianopsia on the right side, with preservation of 1° or 2° of the field toward the blind side, at the macula.

He had another attack five years later, which befell the opposite side and caused complete loss of the remaining halves of each visual field. The second attack did not reach completeness until after three days. When Professor Forster examined the man six weeks later he seemed to be totally blind in every sense. His pupils were about four millimetres wide and gave a feeble reaction to light. This led to inquiry as to possible vision, and it was found that he could read Snellen $1\frac{1}{2}$ very slowly with each eye; distant vision was about $\frac{1}{10}$. Perimetric examination revealed the preservation in each eye of a central field measuring about $2\frac{1}{2}°$ vertically by 3° horizontally and below the horizontal meridian. It would cover a surface 13.5 ctm. (about $5\frac{1}{4}$ inches) in diameter at the distance of 3 m. There was no perception of color. The ophthalmoscopic appearances were normal.

Schweigger's case was a man seventy-five years of age, whom he had treated for years, for chronic conjunctivitis and incipient cataract. I have been permitted to quote it from advance proof sheets by the kindness of Dr. Knapp. In September, 1888, he had an apoplectic attack with left homonymous hemianopsia, not accompanied by other symptoms. In August, 1889, there came another attack with complete homonymous hemianopsia of the opposite side. The whole of both visual fields was destroyed, except a central space in each eye measuring 2° or 3° in diameter. He had retained as the issue of his first attack vision of $\frac{9}{10}$ and $\frac{5}{36}$ in the respective eyes, and this was not made worse by the second attack. Within these fields there was correct color perception. Over the right half fields, the seat of the last attack, there was some perception of light. By the ophthalmoscope nothing abnormal was to be seen.

Still another case is given by Moeli,[3] which occurred in a man affected by dementia paralytica. He had double hemianopsia at successive periods, but on account of his defective mental state an accurate examination of his fields could not be made. But it was evident that he could see within a very small field.

A case by Bouveret [4] of double lesion of the occipital lobes was so soon followed by death as to preclude careful examination of vision. No other functions were damaged. It is not easy to explain the remarkable facts of these cases. Evidently no explanation can be based upon the anastomosis of optic nerve fibres in any of the peripheral parts of the visual apparatus. We have to do with the preservation of that region of the cortical visual centre which supplies the macula lutea. It has been an open question whether the cortical visual region corresponds topographically to the retina and field of vision, and only within four years has any positive evidence been gained. The case published by Hun showed that lesion of the lower half of the cuneus causes loss of function of the upper quadrant of the retina of the same side, *i.e.*, the lower quadrant of the corresponding field is darkened. The demonstrative character of this case is unquestionable, in regard to a topographical correspondence between the retina and the cortex. Whether the inference can be carried to minute details will be considered presently. The cases of Forster and Schweigger are significant, but not demonstrative. Even should an autopsy be obtained in either it would probably prove impossible to identify the intact regions of the cortex. How they can remain intact when the remainder of the region has lost its nutritive supply, is, of course, conjectural. Forster supposes that there must be a special arrangement of vessels to nourish the macular region of the cortex independent of the posterior cerebral arteries and thinks it may come from fine vessels in the pia mater. An attentive anatomical study of this point might give us information.

There are other cases on record of double hemianopsia, but with no note that any vision remained. More light as to the topographical relation between the retina and the cuneus may come from a counterpart to the cases of Forster and Schweigger.[1] A healthy man, aged forty-five, suddenly found reading confused and difficult without any impairment of distant vision. He could read Snellen 1, although not easily and preferred the small words. Color sense was unimpaired. By the ophthalmoscope nothing abnormal. Their were no cerebral symptoms. Pupils and eye muscles normal; urine negative. By the perimeter there was found a small area of blindness on the right half of each field just touching the macula, about equal to twice the diameter of the optic disk, and in outline and extent precisely alike. They were delineated by a test object 1 mm. square. These isolated twin defects remained unchanged for four years under repeated examinations. Their presence was only embarrassing in near work, and in ordinary vision they were unnoticed. In this case there can hardly be any other explanation of the lesion than that it was situated in the cortex, because it was so minute and so well defined and was sudden in its onset. In the medullary (sub-cortical) substance it would hardly have been so small. Its presence seems to compel the inference that the retina and the cortex answer to each other with a remarkable degree of detail. Further proof is to be found in another case (Fig. 34, Taf. x., Wilbrand). A man aged thirty-four had headache for years, the pain not very severe and not to be precisely located. No vomiting or nausea. Six weeks before being examined he awoke with serious disturbance of sight and noticed with closed eyes a brilliant flashing on the right side of each field. V. = $\frac{1}{2}\frac{1}{0}$; the fundus both normal; urine specific gravity 1030, but without sugar. By the perimeter was found an insular defect of oval form in each right field on the horizontal meridian, at the same distance in each eye from the fixation point. The patient was seen only once.

Another case by Wilbrand is figured at three successive periods within five years, during which time only slight changes occurred in the homonymous defects. They reached from the fixation point to the twenty-third circle of latitude on the left side. The only symptom was severe headache. After five years sugar appeared in the urine.

In all these cases of small homonymous, permanent, and similar visual defects, unaccompanied by serious cerebral symptoms, the evidence points almost certainly to a small lesion of the medullary or of the gray matter in the visual centre.

The quadrant defects, such as Hun has reported, are not very rare. I have seen two cases. In one it was not exactly bounded, because a perimeter could not be used in the patient's bed-room. He was a large healthy man, aged sixty-three, a distinguished lawyer. He had for eight years had hyaline casts in the urine and was accus-

[1] Reported by Wilbrand, loc. cit., p. 5.

tomed to examine for them with the microscope. Fourteen years previous he had a small hemorrhage at the macula lutea of the right eye which caused metamorphopsia, but the injury to sight was not permanent—and while a slight zigzag distortion could be noted in fine parallel lines, the defect was not annoying. In April, 1889, he had a cerebral attack whose symptoms were vague, and which came after he had for two days noticed vortices and muscæ floating before him. I was called to him ten days after and found him much depressed in mind; able to converse intelligently, although speech was more than usually slow. He evidently had difficulty in collecting his thoughts. His chief complaint was of confusion of sight and inability to read. There was no paralysis of motion or sensation. There was no headache. There had been pain in the lumbar region. He recognized objects perfectly, could call their names, and remembered the events of the preceding days. His manner was very different from his usual intelligent, although deliberate, character. There was no diplopia; to the ophthalmoscope the eyes were normal. Testing the visual fields with the hand there was found homonymous hemianopsia of the upper two-thirds of the left side. The defect did not include all of the left lower quadrant, and the boundary line could be moderately well defined. I did not see him afterward. He died about seven months later from evident brain lesion, stated to be with signs of softening. There was no autopsy.

Another case of quadrant homonymous hemianopsia which I have noted is as follows: The defect really includes the upper two-thirds of the right half fields, taking in 110°. The man, aged forty, printer, seen at the New York Eye and Ear Infirmary in May, 1887. Indulges freely in alcoholic drink, had been a soldier, and received various slight injuries. Has scars on the head, one over right parietal eminence, one on each side of frontal bone, near fronto-parietal sutures. These were probably received during some of his sprees. Within two years had much headache; denies syphilis and there are no symptoms. On Sunday, May 8, 1887, after having been drunk, noticed that he did not see objects on his right side. Complained that he was afraid of being run over in the street. On examination found to be very myopic, O. D. — 15 D., V. = $\frac{20}{100}$. In the fundus extensive choroidal lesions, both circumpapillary and diffused. In the fields is a homonymous partial sector like hemianopsia on the right side. In the left eye the defect reaches over into the adjacent left side, but here the visual perception remains to a certain degree and is fully accounted for by choroidal changes seen by the ophthalmoscope in the corresponding part of the fundus. Patient is also deaf. He has been observed up to September, 1890, and the visual defect remains unchanged. He suffers constantly from vertigo, which might, perhaps, be attributed to his aural disease, were it not that the symptom has appeared since the eye trouble occurred.

In a case reported by Brill[1] the symptoms were partial hemiplegia and hemianæsthesia on right side, amnesic aphasia and total loss of color perception in both eyes. There must have been right hemiopia although it was not investigated. The lesion was a softened area at apex and lower part of left cuneus, and in adjacent part of gyrus lingualis. It reached within 1.5 ctm. of tip of occipital lobe. The double achromatopsia has great interest and is to be considered in connection with Verrey's case (*vide infra*).

These cases, because of the absence of other cerebral symptoms, point to a lesion of the mesial portion of the occipital lobe. Sector defects may, however, arise from lesions in other parts of the brain. For example, Schweiger[2] gives the case of a woman who, after childbirth fifteen months previous, had hemiplegia and slight aphasia and alexia. All these symptoms passed away. There remained a loss of field on the right side of each eye on the horizontal meridian which included a sector about 20° in breadth. The location of the lesion could not have been cortical exclusively. It may have been subcortical.

A case of sector hemianopsia from tractus lesion is given by Marchand.[3] A student, aged twenty-one years, in blooming health, was examined for myopia and found to have slight double optic neuritis and V. = $\frac{1}{2}$. He was under observation fifteen months and improved in sight nearly to the normal. On his last visit a defect in the upper left quadrant of each eye was discovered. Ten days afterward severe headache occurred, some strabismus, vomiting, coma, and death. At the autopsy a glioma was found in the right temporal lobe near the gyrus hippocampi. It encroached on the outer surface of the tractus at its posterior part, which was softened and reddish yellow, while the rest of it was normal. The defect in the field was caused by the lesion of the tractus.

Another and very recent case of quadrant homonymous defect due to lesion of one tractus is reported by Norris.[4] In this case there were other symptoms besides those of visual disturbance, viz., muscular twitchings, impaired grip of left hand, partial loss of control of left leg, drowsiness, the Wernicke hemianopic pupillary inaction not obtainable, diplopia occurred, and finally complete paralysis of left side. The diagnosis was tumor of the base near the thalamus. At the autopsy a tumor was found at the junction of the right crus cerebri with the temporal lobe. By sections transversely the tumor was found to occupy the white matter within the right occipital and temporal lobes, reaching posteriorly a point just outside the descending horn of the lateral ventricle, anteriorly, and internally at the base it extended to the tuber cinereum and involved the optic tract. Above it reached close to the gray matter of the insula, but did not involve it. It rose about half an inch above the level of the pulvinar; it involved part of the lenticular nucleus, the anterior portion of the internal capsule, and extended laterally to the thalamus. It proved to be a glioma. The complete involvement of the right optic tract in the tumor accounted for the quadrant and otherwise irregular impairment of the visual fields. They were not symmetrical. In the left side more than a quadrant was destroyed and in the right side almost a half, whose border was both oblique and irregular. The extension of the tumor back into the white substance of the occipital lobe doubtless had much to do with the irregular hemiopia.

It therefore follows that absolute localizing value cannot be attributed to sector lesions of the fields. Yet the great probability favors the cortex. In this case the optic neuritis was the only sign until the close of the disease of the nature of the mischief, and this had, at that time, disappeared.

I might call attention to very irregular, but symmetrical types of visual defect. They are found in Schweigger's paper and are quoted in Wilbrand. I have some of my own experience. They may be omitted, except certain very peculiar kinds of which one is noted by Wilbrand and described at length.[5] A man, age not given, short and stout, who had had glycosuria, complained since October, 1888, of dizziness and frontal headache and confused sight. He could see parts of words, and in faces some of the features would be indistinct or invisible and other features clear. The symptoms increasing, he was confined to bed a few days, and during this time visions constantly presented themselves on *the left side*, both with closed and open eyes. He saw landscapes, heads, cats, furniture, etc. The illusions disappeared in a few days. When carefully examined on November 8, 1888, pupils, lids, eye muscles, and fundus were normal. There was correctible myopic astigmatism. The perimeter showed left sided hemianopsia, and by using a small test object 5 mm. square, it was found that the blind half-fields were composed of innumerable insensitive areas separated by openings through

[4] Trans. Am. Ophth. Soc., 1890, p. 470.
[5] Loc cit., p. 54, Taf. ix., Fig. 22.

which the object could be discovered. They could not all be mapped out, but one notable scotoma below the horizon is outlined; the heavy, straight, meridian lines show places where the object was seen uninterruptedly. On the 26th of the same month, with increasing general symptoms, an apoplectic attack occurred with right hemiplegia, coma, and death.

Autopsy twenty hours after. Atheroma of vessels at the base. In removing the brain the hemispheres were torn off at the peduncles, and while both were fragile, the right peduncle showed distinct yellow softening. The chiasm and tractus were normal. The same was true of the cortex, except at the tip of the right occipital lobe, which was softened. The softening occupied the third occipital convolution on the upper and medial surface, but below it reached forward to the fusiform convolution and the gyrus lingualis. Section disclosed a hemorrhagic softening, the size of a hazel nut, in the substance of the medullary matter, and the superjacent cortex had undergone yellowish discoloration. There were no lesions of the internal capsule or of the primary ganglia. The concentric limitation of both the right half-fields must be ascribed to the implication of the whole brain, and especially the other occipital lobe, in functional disturbance.

Wilbrand calls attention to the hallucinations which in his case appeared only in the affected half fields and quotes similar cases from Henschen and Putzel.[1] Dr. Petersen has in two papers recently recorded a similar occurrence. The case of Henschen presented lesions of the cuneus and lingual lobe, and that of Putzel involved the cuneus extensively, as well as the internal capsule and the outer border of the thalamus.

In subcortical lesions, as well as in cortical lesions, hemianopsia may be either complete or incomplete, but Wilbrand's case, so far as it goes, indicates that extreme irregularities in the fields are likely to be due to subcortical lesions.

Another feature of hemianopia requires consideration. The function of sight includes three subdivisions: Perception of light, of color, and of form. If the first be wanting, all are wanting. Given the first, either or both the remaining two may be lacking. Illustrations of such defects occur in hemianopsia. Hemianopic loss of color sense in both eyes is the most frequent among these rather rare cases. Of these, Swanzy[2] enumerates eight in literature and in one case there was an autopsy. Verrey reports it in *Archives d'Ophthalmologie*, tome viii., No. 4, 1888. A lady, aged sixty, had an apoplectic attack, from which she fully recovered, except from the disturbance of sight. There was found absolute color blindness in the right half of each field, with reduced, but not complete loss of light and form sense in the same regions. There was no dyslexia nor mental blindness. During twenty months the condition was found to be the same. Finally she died of another apoplexy. I quote Mr. Swanzy's account of the autopsy: "The cause for death was found in a fresh hemorrhage in the right centrum ovale and lateral ventricle, while an old hemorrhagic cyst in the lower part of the left occipital lobe, extending into the temporal lobe on the mesial side, explained the hemiachromatopsia. This cyst was situated between the floor of the posterior horn of the left lateral ventricle and the basal surface of the occipital lobe. It had occupied the white substance of the inferior occipital convolution, and had almost completely destroyed the white substance of the posterior extremity of the occipito temporal convolutions as well as that of the postero-inferior part of the cuneus. The cyst came nearly to the surface of the cuneus and of the occipito-temporal convolutions, having destroyed the deeper layers of their cortex."

Another case by Siemerling (see Fig. 45, quoted by Wilbrand, loc. cit., p. 144) presented on the right side complete hemianopsia combined with total loss of color sense on both left sides. There was mental blindness, and agraphia and amnesic aphasia. Vision was $\frac{1}{30}$. Within three and a half months vision improved to $\frac{2}{3}$. Color perception returned to the left sides and the mental blindness, alexia, and agraphia disappeared. The right hemianopia continued. There were no other symptoms.

A case of Schoeler's[1] presents on the left side of each field complete color blindness, with the addition in the left half of the right eye of a sector at its lower part where there is no light sense. Patient had bad headache, vertigo, attacks of half sight, swimming before the eyes. No organic lesions. After three months the defect in lower part of the field of the right eye disappeared, but the loss of color sense in the left half fields persisted.

The loss of form sense with retention of light sense is to be determined by testing with letters or simple figures held eccentrically. This examination is not readily made, because we have not a standard in habitual use. One may test by holding up fingers. An abatement in form of sense can sometimes be ascertained.[2]

A case from Schoeler and Uhthoff[3] is in point. A man, aged sixty-eight, double hemianopsia. O. D., fingers at ten feet; O. S., fingers at twelve feet. Fundus normal. In right eye central opacity of cornea. Seven days previous was attacked by severe pain and congestion in the head, until his face became dark red; was blind in both eyes for twenty-four hours, and sight gradually increased to the present amount. Is badly nourished, has dyspnœa. Has stenosis of aortic valves, radial pulse irregular and slow, emphysema of the lungs. Has total loss of color sense in both eyes (no defect formerly). In the right half-fields and in the upper sector of the left half-fields has lost the form sense. In the parts just indicated has light sense, as well as in the rest of the fields. In these parts has subjective flashing which he compares to the rustling of wind in the leaves. Under treatment light sense grew brighter. Had several attacks of headache and vertigo, and temporary blindness. Sight improved until in the eye with corneal opacity vision became $\frac{1}{20}$, in the other $\frac{1}{4}$. He died of heart disease a little more than six months later. The visual fields remained the same.

A case by Brandenberg[4] presented right hemianopia, amnesic alexia of a peculiar kind, viz., he could not read words, but could count figures. The hemianopic loss of sight had respect only to perception of form, but not to perception of light. There was also reduced color sense in the remaining half of the fields. The fourth nerve was paretic and on this account it was believed that a double lesion existed.

The centres for form, light, and color sense are all in the cortex of the occipital lobe. Wilbrand places them one above another; light sense external, form sense intermediate, color sense internal. In this view Reinhardt concurs. Others, viz., Verry, Seguin, and Nothragel, think them to be side by side. As Swanzy says relative hemianopsia can only occur with lesions of the cortex, hemianopsia from lesions elsewhere must always include all the visual perceptions. Those cases of hemianopsia accompanied with some peripheral contractions of the other side of the field are due, according to Swanzy, to cortical lesions. A case by Oliver[5] indicates that this opinion may be erroneous, and the case is extremely interesting from the precision with which the visual symptoms were studied and made to furnish evidence of localization. The earlier symptoms were headache, vertigo, temporary blindness during two years and then followed by spasm of the hand, arm, and to a less degree of the leg. There was right lateral hemianopsia. Three weeks later the remaining half-fields became extremely contracted, this contraction most decided for the left eye.

Vision, $\frac{5}{10}$ O. U. Hemianopic pupillary inaction plainly elicited and showing interference with the sensory motor arc of the pupils. A hemorrhage into the right optic disk. Diagnosis: "Taken in connection with the right hemianæsthesia and right hemiplegia, the ocular changes probably place the lesion near or in the left optic thalamus (pulvinar)." Autopsy revealed a tumor invading the external portion of the left optic thalamus as well as the corpus striatum almost as far as its anterior third. The capsule was not invaded. The left optic tract as far forward as the chiasm was markedly flattened and pressed upon. The right brain was normal. The tumor was hard, and proved to be a glioma with commencing sarcomatous degeneration. The same remarks may apply measurably to subcortical lesions. But we are apt in such cases to meet with decided distant symptoms in hemiplegia, hemianæsthesia, ocular paralyses, etc.

A symptom often concomitant to occipital lesions on the left side has been referred to, viz., mental blindness and with it amnesic aphasia may concur. It is not necessary to enter into any description of it. But that its locality has been pretty nearly determined is proven by the case of McEwen.[1] A man who had received a severe injury a year previous suffered from deep melancholy and homicidal impulses and paroxysms of headache of indefinite seat. The only localizing symptom was mental blindness, which immediately followed the injury and lasted only two weeks. Acting upon this hint the skull was trephined. It was found that a depressed portion of the inner table of the bone pressed upon the posterior part of the supra marginal convolution and the anterior corner of the angular gyrus. When the bone was restored to place the mental condition of the man was greatly relieved. This case gives more precision than any yet published to our knowledge of the region in which to look for the visual memory of objects. I do not find any other approaching it in this regard, except one referred to by Gowers,[2] in which a lesion is located at the angular gyrus of the left hemisphere (reported by Chauffard), and is said to have caused complete mind blindness during the short time the patient lived. For a list of cases, nine in number, in which this symptom was present in greater or less degree see Starr, "Familiar Forms of Nervous Diseases," 1890, p. 64. See also "Wilbrand die Seelenblindheit."

A case of Deutschman's [3] has interest. A boy, aged fifteen, was kicked by a horse upon the left side of the head. Amnesic aphasia occurred, which disappeared in about a week. Then, examined by Professor D——, complete right-sided hemianopsia was found, including light, form, and color sense, and going through the fixation point. In sixteen to eighteen days this passed away and the power of reading became normal. The explanation is thought to be a superficial clot at first compressing the speech centre and settling down afterward upon the visual centre, and when absorbed, function was restored.

Recoveries from hemianopsia are recorded, and even from double hemianopsia. See *British Medical Journal*, Mr. Lang, November 23, 1889. When distant symptoms coexist recovery is not so likely as when these complications are absent.

It would be an unwarrantable omission to say nothing of the behavior of the pupil as aiding the localization of hemianopsia. See Leber in "Graefe and Saemisch Handbook," 1876, Bd. v., iii., 941. Wernicke and Seguin have dwelt upon it. Briefly it is that while in lesions behind the primary ganglia the pupils may act sluggishly, they will respond if light be thrown upon the blind side of the eye. When the lesion is at or in front of the primary ganglia the reaction of the pupil is suspended for the blind halves of the fields.

Swanzy says, "Loss of the pupillary reflex to light, apart from cases of paralysis of the third nerve, is a sign of lesion of the anterior quadrigeminal bodies or of the optic tracts, and may be utilized to distinguish these lesions from others, which may cause loss of sight by implicating both visual paths beyond the corpora quadrigemina, or both visual centres; for in such cases, notwithstanding the amaurosis, the pupil reflex is maintained. Gudden's investigations [1] showed that there are special afferent fibres in the optic nerves and tracts for the pupil-reflex, distinct from those of vision.

"In cases of hemianopsia, similarly, the pupil-reflex serves to establish a diagnosis between a lesion in an optic tract and one further on in the visual path, or in the visual centre, of the same side. For, if the pupil contracts actively to light concentrated on the blind side of the field, the lesion cannot be in the tract, but if it does not react, the lesion must be in the tract." [2]

A notable instance which emphasizes this indication is related by Wernicke (the case was seen by Brieger).[3] A girl, aged nineteen, presented the following important symptoms of focal lesions: Slight hemiparesis of left side, anosmia and total blindness, with double choked disks. The pupils moderately dilated and acting imperfectly under diffused daylight. The blindness, therefore, could not proceed from the optic nerves, but from a central cause, and must be regarded as a double hemianopsia. Anosmia could be looked upon, like the slight hemiparesis, as a distant symptom and be left out of view in localization. Tumor of both occipital lobes was the diagnosis. At the autopsy there was found a tumor in the right temporal lobe which had caused softening in the right occipital lobe, but the left occipital was entirely free. This accounted for the left hemianopia. The right hemianopia was explained by finding a blood-vessel across the left tractus, where it had made a deep furrow and given rise to tissue degeneration. A correct diagnosis of the case might have been made during life if the peculiar hemianopic pupillary inaction [4] had been looked for. This can only be made out by examination with a single light in a dark room, and the light must fall quite obliquely lest by diffusion the sensitive side of the retina be stimulated.

I have omitted detailed reference to other symptoms which appear with hemianopsia, such as the various kinds of paralysis of sensation and motion. They belong to a discussion of cerebral pathology, and my aim has simply been to give prominence to visual disturbances and point out how a more critical observation may render them more productive of information as to the nature of a cerebral lesion.

The points set forth may be thus summarized:

1. The want of uniformity in the exact location of the boundary between the blind and seeing portions of the fields in hemianopsia.

2. The continuance of a small central field in each eye two or three degrees in diameter, in certain cases of double homonymous hemianopsia.

3. Sectorial defects, homonymous in character, are most likely to have origin in the cortex of the occipital lobe, usually in the neighborhood of the cuneus. In these cases there may be absence of other significant symptoms, except, possibly, agraphia, mental blindness, alexia.

4. Sectorial defects may have origin in the subcortical substance of the occipital lobe, but the defective portion of the fields are not likely to be so well defined in boundaries as in 3, and the loss of light sense will be less complete; there may even be irregular spaces where light is recognized, mingled with blind spaces. In these cases hemiplegia, hemianæsthesia, etc., if present, signify proximity of the lesion to the anterior part of the visual radiation of Gratiolet

[3] Tome iii., p. 336.
[4] This phrase is truly descriptive of the facts and to be preferred to "hemiopic pupillary reaction" which is misleading.

5. Sectorial defects, quadrants, or other figures, can arise from lesions of the tractus (cases of Marchand and Norris), but will be accompanied by other significant symptoms pointing to the temporal lobes or to the base, such as paralyses or anæsthesiæ, etc. In these cases, as in all cases of tractus lesion, the blind region includes loss of light-, color-, and form-sense.

6. Loss of either color-sense or of form-sense, with preservation of light-sense, implies lesion of the cortex of the visual centre either, direct or indirect.

7. The hemianopic pupillary inaction signifies that the lesion is at the middle ganglia of the brain, or in front of them, viz., along the tractus, chiasm, or optic nerves.

8. It is certain that a topographical correspondence exists between the cerebral visual centre and the retina, and that it is precise and extends to details. Hun's case proved that the lower part of the cuneus corresponds to the upper part of the opposite halves of the retinæ, and Wilbrand's cases corroborate Hun's, and carry the relationship to smaller regions in the respective localities.

NOTE.—The perimeter of Priestley Smith is, for convenience of manipulation and of registration, to be preferred, while the small hand perimeter of Schweigger is portable and suited to bedside examinations.

ON CERTAIN HYGIENIC MEASURES IN THE TREATMENT OF CATARRHAL AFFECTIONS OF THE UPPER AIR-PASSAGES.

BY F. H. BOSWORTH, M.D.,

PROFESSOR OF DISEASES OF THE THROAT IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE OF NEW YORK.

WHILE entertaining the belief that catarrhal diseases affecting the upper air-tract are, as a rule, not dependent on any constitutional diathesis, but are, on the contrary, purely local in character, and consequently that the prominent indications for treatment lie in the resort to topical remedies, I do not think our whole duty is done by carrying out such indications, in that much can be accomplished, not only in preventing a return of the disease, but in ameliorating local conditions by the enforcement of certain hygienic measures. Indeed, in many cases, especially in young children, I believe these measures are of greater importance even than local applications.

It is a commonly received teaching that catarrhal diseases are the result of taking cold. I have for a long time held the view that, in a majority of instances, a chronic inflammation of the mucous membrane occurs primarily, and that, as the disease develops, a liability to repeated attacks of cold becomes a prominent symptom. The chronic inflammation comes first, and the acute inflammation develops later. While I believe this to be true, we must accept the fact that the local chronic condition is constantly aggravated by the frequently repeated attacks of acute inflammation which result from the taking cold. Anyone suffering from a chronic morbid process is especially liable, under the influence of even a slight exposure, to repeated attacks of acute inflammation. This acute process, moreover, always locates itself in the point of least resistance, viz., whatever region may be the seat of a chronic morbid process. An exposure to cold results in a sore-throat or cold in the head, in the majority of instances, simply because in our climate a large proportion of individuals suffer from a mild chronic inflammation of the nasal mucous membrane or that lining the naso-pharynx.

It becomes an important duty with us, then, to break up this habit of taking cold. We cannot accomplish this by local treatment. We can do much, however, by enforcing certain general hygienic measures. These are, briefly, first, The enforcement of certain common-sense rules in regard to clothing, and second, The judicious use of the bath.

First, Clothing. It is a popular fallacy that we wear clothes to protect ourselves from taking cold. This view of the matter I regard as to a large extent erroneous. The word "cold," as applied to low temperature, possesses an entirely different significance from the same word used in the conventional expression of taking cold. We wear clothes simply to protect the body from low temperatures. For this purpose the rule should be to wear just sufficient clothing for comfort, and no more. There is evidently more risk in overdressing the body than in a deficiency of clothing.

Taking cold is the result of a disturbance of the heat-producing forces in the body. This heat production is in constant operation, and is ordinarily far in excess of requirement. Hence there is a constant radiation of heat from the surface of the body—under ordinary circumstances, by means of the insensible perspiration; under extraordinary circumstances, by sensible or profuse perspiration. The function of perspiration is the great and important function of the skin. We therefore can easily understand how our greatest safeguard in the avoidance of taking cold consists in maintaining the skin in a state of healthy functional activity. An excessive amount of clothing necessarily hampers this function, and the same can be said of improper fabrics.

The most important article of clothing is the underwear, viz., that fabric which lies in immediate contact with the skin. This should be thin, porous, and highly elastic. If we examine the fibres of various textural fabrics, we find silk, linen, cotton, flax, presenting a straight, inelastic fibre. The wool fibre, on the other hand, is curly and highly elastic. When woven into a textural fabric, therefore, wool presents a material which is highly porous, and which, worn next to the skin, interferes with cutaneous perspiration to a less degree than any other known fabric. Our first hygienic rule, then, should be to insist upon our patients suffering from catarrhal diseases wearing wool underwear.

The elasticity and porosity of the fabric being the most important consideration, the question of warmth becomes secondary. Hence we should always give preference to the lighter and thinner material over the heavy and thick flannels which are so frequently worn, and which are to be regarded as exceedingly objectionable.

Another mistake, which I think is a very serious one in the majority of instances, is changing the underwear according to the seasons. It is the habit of most people, perhaps, to make two, three, and even four changes of underwear in the course of the year. This is always a mistake. The same thickness of wear should be maintained throughout the year. Experience teaches us that this is conducive not only to health but to comfort, in that in this way one is warmer in winter and cooler in summer than if the attempt is made to regulate the thickness of the underwear according to the seasons or the height of the thermometer. Practically we spend a large portion of our time, both in summer and in winter, in about the same temperature. In other words, we maintain our living apartments at a temperature of from 68° F. to 70° F. in winter, and, as far as possible, in summer. During cold weather our outer clothing is usually of a heavy, winter character. Add this to the ordinary heavy flannel underwear, and the necessary result is a certain amount of discomfort, with perspiration, while indoors, and a chill on going out into wintry weather.

Recognizing the fact that the selection of underwear should be made entirely with reference to the functions of the skin, and therefore should be porous, permeable, and such as shall admit of the freest circulation of air, the outerwear is selected entirely with reference to comfort, and we put on heavy overcoats and ulsters simply as protection from extreme degrees of cold. The only rule with reference to the outerwear that is important is, that just sufficient should be worn for comfort, and no more. I think we all recognize the fact that the one who habitually overdresses is the one who suffers most from the cold. In other words, the best protection from the rigors of our severe winter is not altogether in thick top-

wear, but in a healthy, vigorous circulation, and this is best maintained where the functions of the skin are least interfered with.

It may be superfluous to add in this connection, and yet I think it is a law we should bear in mind more frequently, that certain portions of the body are inured to the action of cold, such as the face, head, and neck. If the conventionalities of society demand that these should be covered, the covering should be of the lightest possible kind. Nature has provided the scalp with proper covering, and if headwear had never come into vogue, I am confident that alopecia would have been one of the rarest of diseases. Wrapping up the neck to avoid a sore throat, or wearing a thick pad over the chest, a so-called chest-protector, to protect the lungs, is probably one of the most vicious of habits. The protecting covering to the body should be equally distributed over all. Any excessive covering in one portion tends only to weaken this part, rather than help it. Probably the worst possible place to wear a chest protector is over the chest. The best possible place, undoubtedly, would be on the soles of the feet.

Next to the regulation of clothing, and of quite equal importance I think, is the judicious use of the bath, in the prevention of a cold, and still further in the amelioration of catarrhal difficulties. It is a somewhat prevalent idea that we bathe for cleanliness. Man is not an essentially filthy creature, and if that were the only object in a bath, I take it that the health would not seriously suffer if we did not bathe oftener than once a month. Another fallacy, I think, is that the object of the bath is to open the pores of the skin. I do not think that the pores of the skin ordinarily need opening. As a rule, they maintain their own patency without assistance. What the bath does for us, I believe, is mainly to promote a vigorous circulation in the skin and thereby a healthy activity of the heat-regulating function of the skin. This is the immediate effect. But a still further effect is toning up the nerves and invigorating the whole system. This is best accomplished by means of the cold bath. A warm bath is relaxing and depressing, as a rule.

The Russian and Turkish baths, which have come into such general use in late years, I think are based upon a somewhat erroneous system. As we know, one goes into a room heated to a temperature of 150° F. to 180° F., where, remaining for fifteen to twenty minutes, he undergoes a profuse perspiration. He then goes into a rubbing-room, at a temperature of between 70° F. and 80° F., where he is scrubbed with warm water and soap, and subsequently goes under the cold shower. A serious mistake here, of course, is in going in a state of profuse perspiration into a room where the temperature is 40° F. to 50° F. lower. The change involves no little risk of taking cold. If one goes from the hot room to the cold plunge, and remains in the water until the body is sufficiently cool, the Turkish bath is not especially objectionable. Its value, however, is over-estimated. Certainly a patient suffering with catarrhal troubles should not risk it, as a rule. Moreover, it is a great mistake to suppose that a Turkish bath breaks up a cold, as it is far more liable to aggravate it.

In the use of the cold bath, then, I think we possess a remedy of inestimable value in the hygienic treatment of patients suffering with catarrhal diseases. This should be repeated daily, while tolerated. No general rule can be given in regard to this, because every individual is a rule to himself. If a patient emerges from a cold bath with a sense of refreshment and invigoration, it is beneficial. If the reaction does not come on promptly, of course, the measure must be abandoned.

The best method of taking the cold bath I regard as the tub or plunge. As a rule, the immersion need last but from twenty to thirty seconds, after which one should rub the skin off rapidly with a coarse towel and throw over the shoulders a bath-robe to avoid the chill which the wet skin gives rise to. The cold shower is a luxury, and for those who like it can be easily tried. It is a greater shock however, I think, than the tub. Where the shower or plunge is not tolerated, a cold sponging should be resorted to daily, and if still the reaction is not vigorous, I often direct my patients to sponge with cold water to the waist in the evening, and below the waist in the morning, or *vice versa*.

I have thus briefly stated my views as regards the very great value of the cold bath, as well as the proper regulation of clothing in the treatment of catarrhal diseases. I am disposed to think that by enforcing these measures upon our patients suffering with these diseases very much is accomplished, not only in the prevention of colds but in the amelioration of the local conditions. Moreover, I am confident that in cases of catarrhal troubles, especially in young children where the disease is in its incipiency, the progress of the disease may be arrested and a long course of treatment in later life avoided, as well as the serious complications which so often arise with reference to the ears and other parts in these cases. It would not perhaps be wise to say that these directions can be enforced in all cases. In very young children, perhaps, and also in very old persons, other factors must be considered. In the very large majority of patients, however, I am confident that their enforcement will aid us in overcoming many cases of catarrhal trouble which otherwise would prove obstinate and intractable.

26 West Forty-Sixth Street.

ON THE CAUSES OF ECZEMA.[1]

By L. DUNCAN BULKLEY, A.M., M.D.,

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL.

The causes of disease present the most interesting and yet difficult lines of research in medical science, and it must be acknowledged that we are yet far from sound and incontrovertible positions, even in regard to many of the most common affections which we are called upon to treat. While a certain small number of diseases are recognized as resulting from contagion or infection, in but few even of these has the ultimate element whereby the disease is communicated been determined with any degree of certainty; the brilliant demonstrations of various microscopic organisms, micrococci, bacteria, and bacilli, as the undoubted cause of a certain few diseases, stand out as isolated and notable achievements in medical science. But, after all, as yet these discoveries in the laboratory by the microscope have yielded but meagre therapeutical results, and we are obliged in the main to fall back upon our clinical records to afford us the best practical basis upon which to study and combat disease. Of no affection is this more true than of that inflammatory condition of the skin, exhibiting at times most varied appearances, to which has been given the name eczema; here clinical experience and analytical judgment as to cause and effect are everything, for in this disease, of all others, there is no one uniform cause, no single etiological factor which is to be looked for in every case; and consequently, different cases often require very different treatment. But, although the causative elements of eczema are varied, they are still more or less uniform in different classes of cases, and a little observation and care can readily determine on which line therapeutical efforts are to be directed.

A very careful and extended study of some two thousand five hundred cases of eczema in private practice, of which notes have been taken (to say nothing of a still larger number which have been observed in public practice), has convinced me more strongly than ever of the constitutional nature of the disease, and of the very great importance of a careful attention to this aspect of eczema, in order to obtain permanently successful results in its treatment. It is understood, of course, that by this I do not imply, or believe in, any special poison or dyscrasia in eczema, nor give any endorsement of the popular belief in "bad blood" as a cause of the disease; but

[1] Read before the New York State Medical Society, February 5, 1891.

I do assert most emphatically that there are systemic or other changes in the individual at the bottom of the disease-state which exhibits the eruption known as eczema, and that the latter cannot be produced by purely local means alone.

Local irritants may constantly be observed to produce local inflammation of the skin, in varying degree, which tends to pass off as the local cause is removed; this inflamed condition is a dermatitis alone, and must not be confounded with the disease under consideration. Eczema is, indeed, a dermatitis or inflammation of the skin, as are many other cutaneous affections, but it has also other features which characterize and differentiate it as a disease, which need not be dwelt upon here. As well might the erythematous condition excited by a mustard-plaster be called erythema, and the pustular lesions caused by croton oil or tartar emetic be regarded as an impetigo; or a bullous lesion caused by scalding water could be designated a pemphigus quite as rightly as could many of the forms of local dermatitis be classed as eczema. In the large proportion of cases, in private practice at least, no adequate local cause can be discovered for the occurrence and persistence of eczema; and, on the other hand, in numerous cases it can be observed that the same local stimulus which had previously been well borne by the skin, without the production of eczematous lesions, will, under other and altered conditions of the body, give rise even to a severe eczema, which will then persist, and perhaps resist treatment indefinitely.

In studying the causes of eczema, therefore, with a view to a successful management of the disease, I have been more and more led away from the local agencies, so often emphasized strongly by writers, and have, by force of clinical experience, been compelled to regard the general and constitutional state of the patient; and, I may add, when sufficient attention was given to each individual case, I have seldom failed to find evidence sufficient to warrant treatment other than the local means employed, and that to the advantage of the patient.

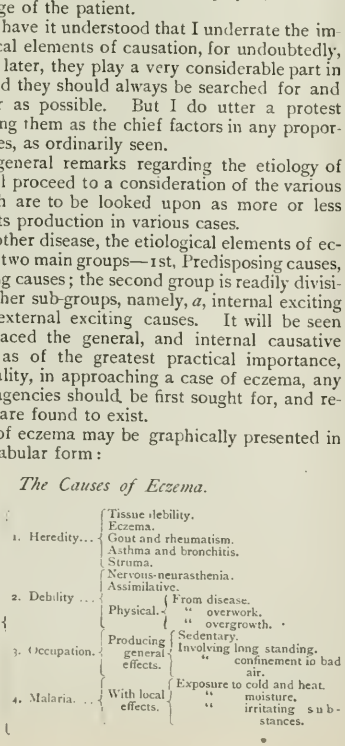
I would not have it understood that I underrate the importance of local elements of causation, for undoubtedly, as will be seen later, they play a very considerable part in many cases, and they should always be searched for and removed as far as possible. But I do utter a protest against regarding them as the chief factors in any proportion of the cases, as ordinarily seen.

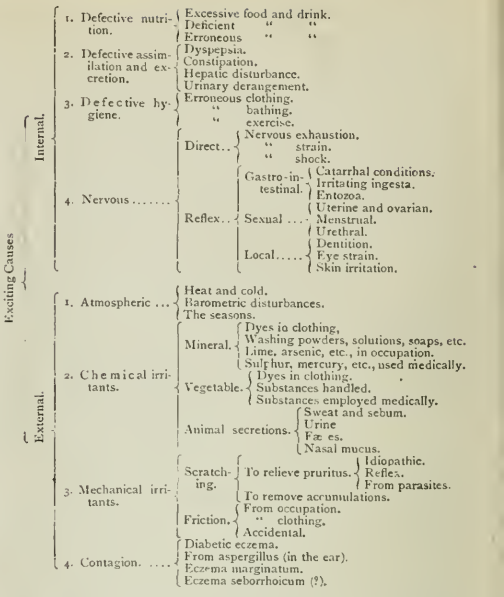
With these general remarks regarding the etiology of eczema, we will proceed to a consideration of the various elements which are to be looked upon as more or less conducive to its production in various cases.

As in every other disease, the etiological elements of eczema belong to two main groups—1st, Predisposing causes, and 2d, exciting causes; the second group is readily divisible into two other sub-groups, namely, *a*, internal exciting causes, and *b*, external exciting causes. It will be seen that I have placed the general, and internal causative elements first, as of the greatest practical importance, although in reality, in approaching a case of eczema, any possible local agencies should be first sought for, and removed if they are found to exist.

The causes of eczema may be graphically presented in the following tabular form:

The Causes of Eczema.





It will be seen that I have here given a pretty long list of elements which are of more or less importance in connection with the causation of eczema. But I assure you that it is not any too long, for there is not a single item on the list which I have not verified to my own satisfaction time and again; and the list is only made up (for the first time, as I believe) from my own experience in dealing with cases of the disease. Moreover, as far as relates to local causes, the list would be very much longer if mention were made of all the possible external agencies which may and do operate in certain instances; but the general classes under which they fall are, I think, mostly included. We will now examine the list a little in detail.

Predisposing Causes.—These we find to be grouped under four main heads, 1. Heredity. 2. Debility. 3. Occupation. 4. Malaria. Careful study will most commonly find one of these elements operating in a large share of cases where eczema is of any great extent or long duration.

1. *Heredity.*—First among the hereditary causes I would place what is here named tissue debility, gotten by inheritance; this represents a certain delicacy of structure with slight resisting power, whereby the skin becomes easily inflamed and has slight tendency to recover tone, and so readily takes on the eczematous process. This, I think, is more commonly an antecedent cause of eczema than is the occurence of the eruption itself in ancestors, which is the next point named; for, in a recent analysis of several thousand cases of eczema I found that in a surprisingly small percentage either the parents, grandparents, or near relatives had suffered from the disease. Gout, rheumatism, and the strumous state have been so long recognized as leading to eczema that I need not dwell upon them. The connection between asthma and bronchitis and eczema is not so generally known; but I have seen gout, asthma, and eczema alternate in so many generations that their connection seems to me undoubted; and bronchitis is continually seen in eczematous patients.

2. *Debility.*—That nervous debility or neurasthenia is a frequent predisposing cause of eczema no one can doubt who will closely study cases over a series of years; innumerable instances could be given of individuals in whom a local irritating agent, which had no injurious effect on the tissues when in perfect health, will operate in a distressing manner when the patient becomes exhausted and has insomnia or other signs of nervous debility.

It will be seen that neurotic conditions are also placed later among the exciting causes of eczema. Physical debility, from disease, overwork, and from rapid development in children is also often seen to predispose to eczema time and again; also debility from assimilative disorders.

3. *Occupation.*—It has occurred to me to see many cases of eczema develop in those who have suddenly, or even gradually, changed their occupation from an active outdoor life to a sedentary one, and in many with sedentary habits it is next to impossible to effect a permanent cure by internal or external measures, or by both combined, unless the habits of life are somewhat changed. Occupations involving long standing, as in laundresses, car-drivers, wood-turners and others, greatly predispose the individuals to eczema of the lower extremities. Continued exposure to the elements predisposes some individuals to eczema of unprotected parts, which, however, may not appear until the addition of some internal exciting cause. We see also cold, heat, and moisture acting as *local* exciting causes of the eruption, and they are therefore also mentioned in this connection later on. Exposure to irritating substances during occupation is also a well recognized element in the active production of eczematous eruptions, as will be dwelt upon later; it may, however, also operate as a predisposing cause, which is inoperative until acting in conjunction with some exciting internal cause.

4. *Malaria.*—This seems to act in several ways as a predisposing cause to eczema, as may frequently be seen by the return of the eruption with each accession or recurrence of malarious influence. I am not disposed, however, to reckon it as an exciting cause, for seldom is the eruption observed in connection with active malarial fevers, but only in those whose systems seem to be pervaded with and altered by the poison. It probably acts secondarily by producing anæmia, nervous disturbance, and liver derangement. Certain it is that some cases of eczema in malarious subjects, or in malarious districts, will not get well and remain so until the malarial element is controlled by proper remedies.

Exciting Causes.—Here we have two classes of agents operating to produce eczema: 1. Those of internal origin, or such as have to do with the patient, as to the diet, mode of life, and the action of various portions of the economy; and, 2. Those of external origin, where the causative elements operate wholly from without, producing inflammatory changes by virtue of local irritant action. Both of these are important in the extreme, and factors in either class may be seen to be followed by eczematous eruption, again and again.

Internal Exciting Causes.—In this class we find that the elements to be considered may also be grouped into four general divisions, according as they relate to, 1. Defective nutrition; 2. Defective assimilation and excretion; 3. Defective hygiene, and, 4. Neuroses.

1. *Defective Nutrition.*—Attacks of eczema are not at all infrequently observed to follow upon errors of diet, and often this is the most important feature to be considered in connection with the disease. The subject is too large a one to enter upon at all fully at the present time, but I wish to emphasize the fact that errors in regard to food and drink, in reference to either, 1, too great quantity (*i.e.*, over-eating and drinking); 2, insufficient quantity, or 3, erroneous kind or quality, should never be neglected in dealing with the disease. Not only is this a very constant factor in infants and young children, but even down to old age the matter must be looked into, or failure in one or the other direction may render all other treatment of relatively little value. The matter of the diet most certainly has much to do with the production and continuance of eczema in a considerable proportion of the cases. Excessive (and often also moderate) use of tobacco will often be found to be followed by exacerbation of the eruption.

2. *Defective Assimilation and Excretion.*—Careful clinical investigation of patients with eczema will show that in a very large proportion of them there exist imperfect assimilation and excretion in a varying degree, and protracted observation of individual cases will demonstrate, time and again, that these functional disturbances have very much to do in causing or precipitating attacks of eczema. This fact is recognized continually by patients, and, I think, more or less by the profession at large; but the tendency is so natural to regard principally the special lesion on the skin, and the difficulty of adjusting proper local measures is often so great, that attention is too often diverted from this line of thought and investigation, and that very much to the detriment of the patient and the hindrance of the cure.

Time and space do not permit of the development of this or other portions of the subject of this paper as could be desired, and I can only urge strongly the most careful attention to this aspect of the study of the causes of eczema; for, I feel confident that it will amply repay all the attention that can be devoted to it in practice.

The dyspepsia present may be of the most varied forms, often so slight as to be overlooked by the patient, or more commonly it is considered a necessary evil. The constipation may also be a natural habit of long duration, which, however, has gradually prepared the way for the systemic disturbances which end in the eruption. The derangements of the liver, so frequently found in eczema patients, belong chiefly to the functional variety, so ably studied by Murchison, which in turn may largely account for the last item in this group, namely, urinary derangements. These latter are often very interesting and instructive in connection with eczema, and repay careful study in individuals, as affording indications for treatment.

As a single illustration of the derangements found in this excretion, I may state that among some 663 examinations relating to 175 cases of eczema, the urine could not be regarded as normal in one half of the cases; and, taking the specific gravity alone, and allowing the wide range of from 1.015 to 1.025, which is regarded by some physiologists as normal, in but 332 instances did it fall even within these limits, in all the other specimens it was above or below this liberal standard of health; 234 specimens showed a specific gravity above 1.025, and 97 that below 1.015. Urinary deposits were also very frequent, uric acid being recorded 108 times, oxalate of lime 157 times, the urates 175 times, and phosphates appeared in excess 140 times.

To anyone who will carefully watch eczema patients for a period of time and closely study the urine in certain cases, it will certainly become apparent that there is more than a casual connection between the eruption and the manifest derangements here referred to.

3. *Defective Hygiene.*—Erroneous clothing will often be an active cause of eczematous inflammation, aside from any irritating character of the same (whether from its textures or dyes), which latter will be mentioned farther on. Over-heating of the skin of infants by excessive wrappings is a fertile cause of eczema of the lower parts, while insufficient clothing may also lead to a chilling of the skin, which is also productive of eruption. While woollen clothing is often removed from eczematous patients, because of its local irritating effects, my experience has firmly convinced me that pure wool should always be worn next to the skin by those who are prone to this eruption, day and night, summer and winter, if possible, in order to secure the greatest immunity from the disease. The sudden chilling of the surface encouraged by cotton in the texture, tends strongly to produce the disease; silk as underclothing does not answer as well as wool. The errors in regard to bathing which will be seen to excite eczema are well known to all, and need not be dwelt upon. Want of proper exercise will frequently be followed by outbreaks of eczema, although, on the other hand, excessive and injudicious exercise will also often be attended with fresh appearances of the eruption.

4. *Neuroses.*—That disturbances of the nervous system may and constantly do play an important part in the active production of eczema, there can be no doubt in the mind of one who has closely observed many cases of the disease, or who has become acquainted with the literature bearing on the subject. This I have fully presented in a recent article on this topic,[1] and will not dwell long on the subject now. It will be seen frequently that prolonged nervous exhaustion, from various causes, will very frequently be followed by attacks of eczema; sometimes this may come only in consequence of loss of sleep for a period, from ordinary causes, sometimes from extra mental worry and work, sometimes simply from the nervous strain incident to business cares or housekeeping, etc. But in many instances the eruption may be observed to recur each time when the same conditions are present.

Sudden and unusual nervous strain will also sometimes be followed quickly by the eruption, and I observed several cases traceable to the excitement incident to the financial crisis on "Black Friday" in Wall Street some time ago.

Nervous and mental shock has been repeatedly seen to be followed by outbreaks of eczema, even in those never previously subject to the disease, and the eruption has been observed to recur also under the same influence.

Eczema also continually appears as a result of reflex nervous disturbances, and these I have divided into such as are owing to, 1, gastro-intestinal; 2, sexual; and 3, local nerve irritation. Time and space forbid developing the proof in regard to these various points, but the most striking illustration is seen in teething infants, where with the accession, or rather the attempt at appearance, of each tooth, we may have recurrence of the eruption on the face or arms.

External Exciting Causes.—The agents or means which may act externally to excite an eczematous eruption, and the circumstances under which it may be produced, are far too numerous to be mentioned individually in a classification, or even in a brief essay; and, moreover, we do not yet know the full measure or number which should be included, for with developing industries, the number is being continually added to, as, for instance, the aniline dyes, which were unknown a few years ago. But, all the local causes may, I think, be grouped under the four general heads of, 1, atmospheric influences; 2, chemical irritants; 3, mechanical irritants; and 4, contagion.

1. *Atmospheric Influences.*—Heat and cold are well-known exciters of the cutaneous circulation, and frequently operate to induce eczema in proper subjects. Barometric disturbances may also be frequently observed to precipitate attacks, and I have had many an eczema patient who could predict a cold snow- or rain-storm, from the warning given by the affected skin. The mere change of the seasons seems to be sufficient in certain individuals to induce an attack, and some patients will have fresh outbreaks of the eruption at definite periods of the year; but in all my studies I have never been able to satisfy myself that in general the eruption was much more frequent at one season than another; some patients are invariably worse in warm weather, others always suffer more in cold weather.

2. *Chemical Irritants.*—These are found to belong to three classes, 1, mineral; 2, vegetable; and 3, animal; and the number and variety of irritating agencies which may be included here are very great, and they can receive only the briefest mention. 1. Mineral irritants are found in articles dyed with the aniline colors, such as socks, gloves, hat-bands, etc. Various substances used in the trades and arts, such as arsenic, bichromate of potash, mercury, alkalies, etc., are often seen to be followed by eczema; also irritants such as lime, in bricklayers and plasterers, while a host of other illustrations could be given, did space permit. Mineral and vegetable substances employed medicinally may also afford the starting point for eczema: thus, we often see it after sulphur and mercurial baths, as also following the irritation of various plasters, arnica, stimulating liniments, etc., indeed there is almost no end to the list of local irritating agencies which at one time or another have caused the lighting up of eczema. The various washing powders and solutions, as also many varieties of soap, will now and again excite the eruption in tender skins, on suitable subjects; the "washerwoman's itch" is too well known to require more than a single mention. 2. Vegetable irritants are also found in certain dyes in clothing, as also in substances handled or brought in contact with the parts, either in occupation, medicinally, or in ordinary life. 3. Irritants of animal origin may be of external origin, but are chiefly those which arise from the secretions from the individual affected. The latter include irritation produced by retained sweat and sebum, seen especially in the folds of the body, that from urine and fæces, occurring principally in infants, and the eczematous inflammation often seen on the lip from disordered nasal mucus.

3. *Mechanical Irritants.*—Direct mechanical irritation is a frequent cause of the appearance and spread of eczema, and foremost here must be placed scratching, which is directly or indirectly responsible for a considerable proportion of the area of eczematous surface seen in many cases. In a skin predisposed to the eruption, and in an individual prepared for the same, a very small amount of scratching can very readily cause a patch or surface of eczema to be developed in almost any desired locality, as can be experimentally demonstrated with the greatest ease. In those subject to eczema more or less pruritus will occur here and there, which if not touched will not develop into any distinct lesion. But generally this is not left alone, for the spot is torn and rubbed until a raw surface appears; this then becomes coated with an exudate, which is again torn off, and the process is repeated indefinitely, with the production of infiltration or thickening in the patch, and the eruption is established in that locality, and then the skin is slow to return to the normal state. If at almost any period of the process all local irritation is taken away, and the part is left absolutely untouched, much of the lesion present will disappear.

This scratching, then, may be practised to relieve pruritus, which may be either, 1, idiopathic; 2, reflex; or 3, from parasites; finally, the local irritation may occur as a result of attempting to relieve accumulations, as in the nose or ear, or crusts which may form on any part of the body, or on the scalp of new-born children.

The second mode of mechanical irritation is from friction, which may arise from harsh or ill-fitting clothing, also from trusses and suspensory bandages, it may also occur in the course of occupation, or may be accidental, as for example, from horseback riding, etc. All of these many forms of mechanical irritation must be recognized and removed if they exist, or treatment will be of but partial and temporary benefit.

4. *Contagion.*—Up to the present time four conditions of the skin classed as eczema are recognized to be due to contagion by means of vegetable microscopic organisms. These are, 1, diabetic eczema; 2, that from aspergillus in the ear; 3, eczema marginatum; and 4, eczema seborrhoicum (?). About the genitals of those affected with glycosuria it is not at all infrequent to find a rebellious form of moist eruption, exceedingly itchy, which is due to the irritation caused by the growth in the skin of the sugar fungus, torula cerevisiæ. In certain obstinate, itching, eczematous conditions of the external auditory canal, the eruption will be found to be due to the presence of the aspergillus. The distinctly marginated eruption often seen about the fork of the thighs, and also in the axillæ, and occasionally elsewhere, where two cutaneous surfaces touch one another, is often spoken of as eczema marginatum, and is due to the presence of the trichophyton tonsurans; it is in reality one of the forms

[1] The Medical News, Philadelphia, January 31, and February 7, 1891

of ringworm, but the eczema element in it is often very considerable, and the common name above referred to will often seem most appropriate. Lastly, we have the eruption about which so much has been written of late years, the eczema seborrhoicum of Unna. As yet it has not been determined at all accurately what the infectious element is, if any, in this eruption, but many clinical features seem to point to the supposition that a micro-organism is the essential cause of the appearance of the lesions.

In presenting thus briefly a systematic sketch of the cause of eczema I am conscious that the work is far from complete, and that it but imperfectly represents the agencies which often combine to produce this protean eruption. But the desire has been to simplify the subject, and, naturally, time and space have prevented the presentation of much that could with advantage be added in connection with many of the points here presented; it is also desired that this paper be suggestive of the need of further study and observation of the true causes of eczema, and it is believed that the framework of a classification of them here exhibited may be made to include all the elements of importance in this connection.

It will be seen, then, that eczema is not always a very simple affair, quite unworthy of serious attention, but that it is one of the great diseases, often having to do with the most varied departures from health in almost every portion of the system. Our present study will, therefore, make more clear the words of Wilson, "to be a successful practitioner in the treatment of eczema a medical man must be an accomplished physician. . . . In a word, the highest and best qualities of medical art and science must be put in practice with foresight and discretion for the treatment of an eczema." If, however, we do not fully accept such a broad statement, I think that our present study will at least explain why many cases of eczema do not recover under the routine treatment of arsenic and oxide of zinc ointment.

4 East Thirty-seventh Street.

AMYL NITRITE AS AN ANTIDOTE TO CHLOROFORM.

By F. A. BURRALL, M.D.,

ex-visiting physician to the presbyterian and charity hospitals, new york city.

In the Medical Record of August 16, 1890, is a brief report of Professor Wood's address on "Anæsthesia," delivered before the International Medical Congress. Regarding the treatment of chloroform-poisoning it is stated that "the author's experiments proved that amyl nitrite, caffeine, and atropine were of little use." This opinion might have been even more comprehensive with a qualification, and it might have been said that in many cases of impending death from chloroform no known remedies are of any avail, especially if there is any delay in their administration. The motto *Bis dat qui citò dat*, could never be more appropriately placed than in such surroundings. Some time since I wrote to a physician who was present at a case of death from chloroform, in which it was stated that the nitrite of amyl was used in vain, for the purpose of inquiring the details of its administration. The reply was that the drug was "used very late, and when all chance of being of any service was apparently over." When the advent of death is so rapid as sometimes occurs after the inhalation of chloroform, every lost instant may prove the cause of a fatal result, and any remedies to be of use must be applied immediately. The opinions and experiments of others on this subject, as well as my own studies and experiments in the same direction, have led me to believe that with arrangements for prompt administration of amyl nitrite lives may be saved which otherwise would be lost, and that there is an essential antagonism between the effects of the two agents.

Professor Wood regards digitalis as of all remedies the most powerful in stimulating the circulation, and an opinion from such a distinguished source, based on study and experience, cannot but be received with due consideration. I have not seen the report of any cases in which digitalis has been used as an antidote to chloroform, and can only depend upon this statement as to its properties. Like the amyl nitrite, digitalis also dilates blood-vessels. Whether digitalis acts with that remarkable rapidity which is characteristic of amyl nitrite I do not know; digitalis has the disadvantage of requiring the hypodermic syringe for its administration, while amyl nitrite can be given hypodermically or by inhalation.

I have long been interested in amyl nitrite, and there is an unusual attraction in the promptness and positiveness of its effects, which has secured for it a permanent place in the materia medica. I was the first to suggest the use of it as an antidote to the syncope of chloroform, in a communication to the New York *Medical Gazette* of June 11, 1870. In another article to the Medical Record of July 20, 1878, on the use of nitrite of amyl in chloroform-poisoning, I further took the view that "the effect which it exerts of overcoming stasis seems to be its most important function. While in the syncope arising from chloroform, the nitrite of amyl exerts its antidotal properties by opening the arterial channels and admitting blood to the brain, in asphyxia, the pulmonary stasis is also overcome, and arterialization follows."[1]

In looking over the medical journals I have met with reports of a number of cases in which it may fairly be claimed that death from chloroform inhalation has been averted by the use of amyl nitrite, and I have subjoined a list of them which I have never fully published before. Deaths from chloroform seem to me to be less frequent than formerly, and I think a majority of the profession still regard it as uncertain and dangerous. Hence none of the cases submitted here are very recent.

They are as follows:

1. Dr. Rufus B. Hinton.[2] Opening of whitlow, Squibb's chloroform used. Patient became deathly pale and ceased breathing. Tongue was drawn forward with tenaculum and five drops of amyl nitrite applied to nose and mouth. Flushing of face with violent beating of carotid ensued. Recovery.

2. Dr. C. Bader, of Guy's Hospital.[3] Iridectomy. A mixture of alcohol, ether, and chloroform given. Patient "suddenly became pale, deeply insensible, with pulse and respiration very defective. Lint with a few (three) drops of amyl nitrite over nose and mouth." Deep inspiration, flushed face, quick pulse, and return of sensibility followed.

3. Dr. C. Bader. Given chloroform to a pale, fat boy, with blue lips and cheeks. Patient became suddenly very faint, the blood turning black, and the breathing becoming very imperfect. Ten drops of amyl nitrite over mouth and nose. "Same quick result, with vomiting, following inhalation of three drops of nitrite of amyl."

4. Dr. Bader. Given chloroform to a middle-aged woman, who suddenly became blue in the face and stertorous, the tongue falling back. Ten drops amyl nitrite on lint over mouth and nose. In a few seconds blueness and stertor were succeeded by good color, regular breathing, and sickness and vomiting, although patient had taken no food for several hours.

5. Dr. G. R. Fowler, of Brooklyn, L. I. Chloroform given for the operation of tracheotomy in a case of diphtheria. During the operation sudden pallor came over child's face, the chin dropped, the pupils became widely dilated, the radial pulse became imperceptible, and respiration ceased. Amyl nitrite was placed over child's nostrils, and artificial respiration practised. The lips and face became rosy; pulse and respiration reappeared.

6. Dr. F. W. Rockwell, of Brooklyn, L. I. Chloro-

[2] Philadelphia Medical Times, July 31, 1875.
[3] London Lancet, May 8, 1875.

form given in a case of puerperal convulsions. Patient became cyanotic and respiration ceased. Nitrite of amyl administered, and Dr. Rockwell was of opinion that "the amyl in this case saved my patient's life."

7. Dr. S. Baruch,[1] now of New York City. Chloroform given in a case of operation for abscission of prepuce. Face became blanched, respiration ceased, no radial pulse, and lower jaw fell. Amyl nitrite given and artificial respiration practised. After third inspiration "a whiff of nitrite of amyl seemed to enter the lungs, and the patient's face lost its pallor." Recovery.

8. Dr. John Burke,[2] New York City. Chloroform given for operation on the vagina. Patient became suddenly blanched, apparently dead, pulse and respiration ceased. Amyl nitrite administered on handkerchief. Face became reddened, breathing returned, and patient recovered.

9. Dr. R. Riddell, Belfast.[3] "One of the passengers had brought some chloroform on board for toothache. I was summoned in haste to her cabin, and found her quite insensible; pulse not perceptible, and evidently dying. Fortunately, though the nitrite was not in the ship's surgery, I had brought some to experiment with. After inhaling a few drops the heart's action was quickened and strengthened. Three or four times we had to repeat the inhalations before she was out of danger. It is so antagonistic to chloroform that I am of the opinion that it should be at hand at every operation in which chloroform is given."

10. Dr. Edward R. Mayer, of Wilkesbarre, Pa., informed me recently that he has successfully used amyl nitrite for the purpose of averting impending danger from chloroform in a number of instances.

Dr. George F. Shrady, in a paper on "Abuses of Etherization" (MEDICAL RECORD, February 23, 1886), says, "The most trustworthy means of resuscitating desperate cases are artificial respiration, hypodermic stimulation, inhalation of nitrite of amyl, and inversion of the body."

It is, perhaps, unnecessary to add that an interne in one of our hospitals told me that it was the custom, in the hospital with which he was connected, to hasten the progress to consciousness of patients who had been taking chloroform by inhalations of nitrite of amyl.

As has been previously observed, amyl nitrite may be administered hypodermically or by inhalation, in from five to ten drop doses, without fear of any injurious result. The evidence is quite full and clear on this point, and I do not think it necessary to refer to individual authorities.

It is rather a general belief that traction upon the tongue raises the epiglottis and opens the larynx for a freer passage of air. In the report of the address before the International Medical Congress which has suggested this paper, it is advised that the tongue should be drawn forward, as one of the measures to be adopted in averting threatened death during anæsthesia. But Dr. Benjamin Howard has demonstrated before the Royal College of Surgeons, England, and before other learned bodies,[4] that "1. Contrary to universal belief, traction of the tongue cannot raise the epiglottis. 2. By sufficient extension of the head and neck, whether by volition, instinct, reflex action, or by the effort of another—whether in the healthy, the dying, or the dead—the epiglottis is instantly and beyond prevention made completely erect. 3. By complete extension of the head and neck the tongue and velum are, as respiratory obstructions, simultaneously with the epiglottis, removed, and without a moment's delay the entire air-way can be straightened, enlarged, and be made free throughout, by the nearest person."

[4] Braithwaite, lxxxiv., from Lancet, October 27, 1839, p. 819.

The experiments of Schuler[1] and Pick[2] have shown that chloroform causes contraction and diminished pulsation of cerebral vessels, while amyl nitrite produces relaxation of all unstriped muscular fibre, especially that of blood-vessels, and causes their rapid dilatation. Schiff found, also, that vascular often precedes respiratory paralysis, as a result of the inhalation of chloroform. In Dr. J. A. McWilliams'[3] experiments made on cats for the purpose of investigating the comparative effects of ether and chloroform, he found that three cats collapsed suddenly, while respiration was going on regularly and efficiently. "The pulse was found in each case to be imperceptible, and after respiration had gone on for some time the heart was found in each case, on opening the chest, to be contracting so feebly as to be entirely ineffectual in propelling the blood. All the animals were resuscitated by rhythmic compression of the heart with the thumb and finger. As a general rule, however, in death by chloroform, respiration ceased before any such failure of the heart's action as to be incompatible with life." It was also found that "an amount of chloroform that could be given with safety during quiet respiration speedily produced alarming symptoms when respiration became rapid and deep." Further than this, it was observed that dilatation of all the cavities of the heart frequently occurred at an early period of the administration of the anæsthetic. This was usually accompanied by a fall of blood-pressure, but there was no interference with the regularity of the heart's action. Firm compression of the abdominal aorta was the most effectual way of increasing the blood-pressure in the carotids when it had fallen to a dangerous degree.

In deciding upon remedial measures we must depend on both the observations of scientists and the teachings of clinical experience. With such light thrown upon the action of chloroform, let us suppose that a patient who is inhaling chloroform suddenly develops dangerous symptoms. Of such symptoms a tendency to fatal syncope is the most frequent. What conditions are present under such circumstances, and what shall be done to avert a fatal issue? We may hold that the cerebral vessels are contracted, and the central nervous system is losing the blood supply on which its activity depends. Circulation and respiration are faltering and death may occur suddenly at any moment. It is not a time for the application of any one method or remedy, but all the usual aids, as well as the reserves of science, should be immediately employed. The first indications are to revive circulation and respiration, since what arouses one seems to awaken the other. I think that, as nearly simultaneously as possible, the head should be lowered, the neck extended,[4] nitrite of amyl given hypodermically or by inhalation, and artificial respiration practised by the Silvester method, since this method is the most convenient. It should not be forgotten that pressure on the abdominal aorta increases the blood-pressure in the carotid. If asphyxia be present, it would seem that the neck should be extended, and the head raised higher than the feet.

This paper would not have made its appearance, as I have already written several articles upon the subject, but I thought it a good opportunity to bring forward these cases in which amyl nitrite has saved life, and thus present the claims of a drug which, up to the present time, has a better clinical record as an antidote to chloroform than any other with which I am familiar.

[4] Dr. Robert F. Weir (MEDICAL RECORD, February 23, 1889) has stated that in some cases in which he had used Dr. Howard's method of opening the glottis, by allowing the patient's head to fall back over the end of the table, he did not find it satisfactory. On the other hand, Dr. Howard's demonstrations were regarded as conclusive. Practising auto-laryngoscopy, I have seen the larynx well open and the epiglottis erect when the neck was extended, but my experiments have been few. Probably some improvement may be made in the method of carrying out the principles laid down by Dr. Howard.

Clinical Department.

SOME COMMENTS ON THE PRESENT THERAPY OF PULMONARY TUBERCULOSIS.

By J. M. W. KITCHEN, M.D.,

NEW YORK.

The Koch method of treating tuberculosis has had its swing of exaggerated importance. It now looks as if the return swing is reaching the length of undeserving condemnation. This is a natural sequence to the hyper-estimation of the remedy, and hopes as to its potency. Professor Koch's own declarations were not sufficiently optimistic to warrant the exalted ideas of the remedy's power that have been formed so widely. It is probable that such over-estimation has been largely due to the lack of appreciation of—or forgetfulness of—the fact that the specific bacillus is not the sole etiological factor in tuberculosis. The great majority of observers will agree that the disease is also due to a pre-existent state of pulmonary or general constitutional mal-nourishment. It is not beyond belief that a strong, healthy individual may become infected under exceptional conditions. But the reverse is certainly the rule. A condition of vigorous health apparently does not confer immunity from the invasion of some disease-germs, but this does not hold in regard to tuberculosis; and, as is well known, a vigorous state of general health has been the only accepted condition of cure for the disease—a condition that of itself has frequently effected cures without medical interference. In the light of the knowledge that the remedy did not kill the bacillus, it has been irrational to expect that the remedy could do more than be of assistance in the general treatment. That it has a certain adjuvant value in the treatment seems to have been already proved. From the experience now accumulated, an outline of its probable usefulness is beginning to be discernible, and some practical guiding rules may be formulated. It has some diagnostic value, but probably not as much as was expected. Some cases of incipient tuberculosis are therapeutically hopeful without its use. Hygienic and tonic treatment alone suffice to effect a cure in these cases when the circumstances of the patient admit of such treatment for a sufficiently lengthy period. In view of the present uncertainty as to the ultimate effect of the remedy, it would seem wise not to use it in such cases. In certain other incipient cases, equally hopeful, except that the patients might be deficient in pecuniary circumstances, or be commencing the course of their disease at the beginning of an inclement season, and when time is a question of prime importance, it would seem that the help of the remedy should be invoked. I am inclined to think that this remedy should not be used in cases where the general tone and resisting qualities of the tissues have not been elevated and established to, and in, a somewhat vigorous status at the time of the inoculation. Otherwise, inasmuch as the bacilli are not destroyed, they would be likely to become more widely diffused and to infect new territory. The question of time is of the utmost importance in many cases. Any case needs every advantage that can be brought to bear on the individual, and it would seem to be a hopeless outlook if the patient has not, in particular, decided climatic and other hygienic advantages. Some patients are enabled to give themselves good environments of this nature for a short time only. Others pass over the hopeful period at the beginning of winter. From a therapeutic point of view there are numerous good summer climates; but there are no very good winter climates in practically accessible and otherwise desirable localities. The best of which I have knowledge is the elevated strip of pine land beginning at about fifty miles below Macon, Ga., and extending into Northwest Florida. The winter climate of this section is much the same as that of Lakewood, N. J., during October. Now, if this class of individuals can have assistance at just the critical time their outlook becomes hopeful. It would seem that the most valuable action of parataloid is to hasten the detachment and expulsion from the body of the pathological products of the process. It quickly effects a result that would follow more slowly in the ordinary course of the disease. Many cases are lost because of the wear and tear of a long-continued struggle with the disease. They probably could be saved if the fight were shortened. In such cases it seems that Koch's remedy will be valuable. There is another class of cases in which it is early plainly evident that all hygienic and other usual methods of treatment will not be successful. It is surely the duty of the physician to give the patient the benefit of the possibility that such treatment in conjunction with inoculation may prove successful in such cases. There is, alas, a large class so far progressed in the disease that interference with parataloid would, with little doubt, only hasten the inevitable end.

Hygiene must, in all probability, ever remain the fundamental resource in any treatment of this disease. Because of its very nature, whatever means of treatment are adopted, there must be a background of constitutional strength and tissue invulnerability to work on. The sources of vitality are pure air, reconstructive and combustible aliment, physical exercise, and certain sources of stimulation. These must be ardently invoked in the treatment of this disease, especially as it must be more or less protracted.

That word stimulation recalls a belief that there are several probable errors quite commonly practised in the usual treatment of pulmonary tuberculosis. One is, that the patient is too frequently gorged with nourishment, and the digestive apparatus consequently kept in a state of disorder. I have seen a young phthisical girl, who always had a clean tongue, increase in stature and improve in health for several years, subsisting mostly on infusions of tea and coffee, but with so small a supply of reconstructive and carbonaceous foods that I decline stating the amount, fearing impeachment of my veracity, or of my powers of observation. The observation has taught me a lesson. A certain strength of arterial tension is desirable, but that can be gained by a frequent liberal supply of pure water. Milk is a good food, and possibly more than three meals per diem is frequently desirable; but very frequently better nutrition can be gained by a decrease in food, both as to frequency in the giving and as to the quantity consumed. The food should be immediately adapted to the digestive ability of the patient, in quality as well as in quantity, rather than to attempt to stimulate the digestive apparatus to accomplish work of which it is only capable during a general condition of vigorous health. Another probable error is the giving of alcohol as a beverage, under the belief that when thus consumed it is a source of force. Stimulation is necessary for life; but there are good and bad methods of stimulation, and unwisely chosen avenues for introducing stimulation to the body. Alcohol, without doubt, can be used so that its preponderating effect is stimulating; but as ordinarily used as a medicinal beverage its preponderating effect is anæsthetic, narcotic, and depressing. The aromatic and flavoring ethers, etc., in certain wines and liquors, are of a certain value in stimulating the nutritive processes, and may be used to that end; but the ultimate preponderating effect of alcohol in the general system is not of advantage in the curative treatment of phthisis; and for such treatment there are better tonic remedies than alcohol. Its use in the alleviative treatment of the disease is another matter.

Alcohol is a wonderful fluid. Perhaps some day a genius will discover means to so strongly antagonize its poisonous effect on the nervous system that we will be able to soak the general system with it so fully, and for so long a time, that even entrenched bacilli must succumb to its penetrating effect. The suggestion is given to the world for what it is worth. Perhaps some day that same world will more completely realize than it does at present the value of preventing disease. There is little

doubt that multitudes of the victims of tuberculosis could be shielded from its acquisition if the health status of such individuals were elevated by the administration of a simple tonic at just the right time. The world will understand some day that an individual in a depreciated state of vitality is in a condition of great danger.

A CASE OF TRAUMATIC PARALYSIS OF THE ABDUCENT AND OCULO-MOTOR NERVES.

By F. E. D'OENCH, M.D.,

NEW YORK.

C. K——, aged sixteen, was sent to me on account of an injury to the right eye which he had received three days before. Some boys had been shooting at a target, using as arrows the ribs of an umbrella, which they had flattened at one end so that they could be placed upon the string. One of these arrows they had left sticking in the target, and in the darkness the young man came forcibly in contact with it. It struck him on the upper lid near the inner canthus and close to the orbital margin, producing a superficial wound about the size of a hempseed. Almost immediately afterward he noticed that he saw double. When I first saw him, three days later, there was a small, subconjunctival hemorrhage in the lower inner part of the eye; the fundus was normal, the pupil reacted promptly, and V. = $\frac{20}{30}$. The eye could be moved outward not quite to the median line, and the mobility upward was also restricted. A candle placed in the median line in the plane of the internal and external recti muscles appeared double, the upper image being about 6″ above the lower and 4″ to the right, and its upper end tipping slightly to the left. This condition of affairs slowly improved, but fully two months elapsed before normal mobility was re established and the diplopia had completely disappeared.

More serious lesions, such as fracture of the bone, tearing of the nerves, etc., can be excluded as the cause on account of the course of the affection, and the paralysis can probably be attributed to a hemorrhage at the apex of the orbit, compressing the abducent and part of the oculo-motor nerves.

SULPHATE OF ZINC IN DIPHTHERIA.

By S. L. KILMER, M.D.,

SOUTH BEND, IND.

The article on diphtheria in the MEDICAL RECORD of February 28th induces me to report the success I lately had in that affection by the use of sulphate of zinc. On Sunday, February 8, 1891, I was called eight miles into the country to see two children supposed to have a severe cold with perhaps pneumonia. Upon my arrival they were found to be suffering from diphtheria, the one, a boy of nine years, having a temperature of 103° F., tongue heavily furred and a typical diphtheritic exudate covering both tonsils and all the visible portions of the mucous membrane of the palate and pharynx. The child had been sick three or four days. The other patient, a girl of eleven years, had been sick two days. She had a temperature of 100° F., tongue slightly furred, throat congested, with one small patch of grayish exudate upon the right tonsil not exceeding a line in diameter.

The mother of the children had about a week or ten days previously returned from assisting in nursing the children of her brother, who resided some eight miles from them; five of her brother's children were sick of diphtheria and three of them died of it, the disease seeming to have been especially malignant.

As to the treatment of these cases details will be omitted. Suffice it to say that it was identical in the two cases, with one exception, viz., in preparing a gargle for the boy, who was so much worse off than his sister, the family all watching the procedure, it seemed appropriate that his treatment should be different, in some respects at least, from that of his sister, and for this reason was added to his gargle (an ordinary tumblerful of water) about fifteen or twenty grains of sulphate of zinc. Upon my visit the next day, my surprise was great to find that about one half of the membrane (diphtheritic) had disappeared from the boy's throat, while the diphtheritic membrane in the girl's throat had enlarged to about half an inch in diameter, and the throat in every way looked worse. The same treatment was continued another twenty-four hours, at the expiration of which time the exudate had entirely disappeared from the boy's mouth and throat, while in the girl's throat it had again at least doubled in quantity, and the general appearance of the throat was much worse. Believing then that the zinc sulphate was entitled to credit for the boy's rapidly improved condition, the girl was supplied with a gargle identical with that which the boy had been using, and twenty four hours later not only had the diphtheritic membrane disappeared entirely, but all the swelling and distress had gone also, and both patients were now convalescent and speedily recovered. No further opportunity for testing the efficacy of this remedy in diphtheria has been afforded. Whether future trials will give equally favorable results remains to be proven. Some corroborative evidence of its efficacy as an antiseptic in zymotic diseases has been afforded me in cases of exanthematous suppurating inflammations about the finger-tips, in which it has since been tried, where its beneficial results were manifested very promptly. I consider the remedy deserving of a thorough test, and shall be happy to learn of its results in the practice of other physicians.

HOT DILUTE SULPHUROUS ACID IN THE TREATMENT OF DIPHTHERIA.

By FRED N. OGDEN, M.D.,

PASSED ASSISTANT SURGEON, U. S. N.

Some time since, on one of our training ships, while she was lying in the harbor of Newport, R. I., there occurred several cases of diphtheria. As is customary, when practicable, in such instances in the U. S. N., the cases were put as far away from the remainder of the crew as possible, and it so happened that on Coasters' Island there was a building which answered the purpose of a hospital, and to this place the patients were sent as soon as the disease developed; thus by prompt isolation and careful disinfection the number was held down to the minimum. There were in all five cases, and I shall speak of them as Nos. 1, 2, 3, 4, and 5. Being in quarantine in the hospital, I had excellent opportunities of watching the progress of the disease in each case.

Cases 1 and 2 reported within forty-eight hours of each other, and when the diagnosis was made they were sent ashore.

No. 1. Temperature, 104° F., face flushed, throat sore, conjunctivæ injected, tongue coated, general malaise. This boy had been on shore visiting friends, and it was known that there were several cases of diphtheria in the town of Newport at the time. His throat showed the usual profuse congestion of diphtheria; there was general depression and a rapid pulse. The condition became aggravated, and on the second day there was a slight deposit on the pillars of the fauces and right tonsil; great pain on deglutition; pulse and temperature the same. On the third day the membrane, which had spread rapidly, extended over the soft palate, the walls of the pharynx, and a considerable way down. The voice was with difficulty heard, and was hoarse and of the character usually developed in such cases; there was considerable coryza and slight nose-bleed. Respiration, 27. The tonsils and the glands at the angles of the jaw were much swollen. Patient mildly delirious.

During this time the treatment had been both constitutional and local, as follows: Hydrarg. submur., 0.7

gm.; sodii bicarb., 0.7 gm., followed in eight hours by a seidlitz powder. On the second day the throat was swabbed out with argenti nit., 2.0 gm.; aquæ, 16 c.c.; and chlorate of potash and muriate tincture of iron were given in large doses when the membrane appeared. Dilute sulphurous acid (4.0 c.c. to water 64.00 c.c.) was given as a gargle, the throat and mouth were also sponged with a weak solution of carbolic acid. In this case the membrane was very extensive in both directions, it was very tenacious and occasioned considerable hemorrhage when portions of it were detached. During the night of the third day the throat symptoms were so severe that it was thought that tracheotomy would be necessary before morning, and all preparations were made; before resorting to this measure it was determined to try boiling water with the sulphurous acid instead of water of the ordinary temperature, and to double the quantity of the acid; this was done and the patient being thoroughly aroused used the gargle for several minutes and repeated it every thirty minutes thereafter; he became easier almost immediately, the respiration becoming less labored and much slower; in a few hours the patient passed into a quiet sleep, and from that moment began to improve.

The gargle was repeated every hour after the patient showed signs of improvement, and in the morning the membrane had not only ceased to form but had to a great extent disappeared.

The delirium had passed away, and the boy was able to pursue the treatment properly and to take nourishment and stimulants with ease. Sulphur was burned continuously in the rooms, and every precaution was taken to prevent the spread of the contagion from this focus. Case 2 was almost identical with Case No. 1 except that it was not so severe, due, as it was thought, to the fact that the hot gargle was commenced sooner by twenty-four hours than in Case No. 1. In the remaining three cases the membrane was not allowed to extend, but was promptly checked and dissipated, so no trouble at all was experienced. In these cases the constitutional remedies were also pushed with vigor. All of these patients recovered, and I have used the same treatment since with the most gratifying results. I give it for what it is worth; and surely, although the number of cases cited is small, the success obtained speaks well for iron and chlorate of potash internally and dilute sulphurous acid (1.600 c.c. to boiling water 128.00 c.c.) as a gargle every thirty minutes to every hour. The most liberal diet and the free exhibition of stimulants, as is well known, aid much in the treatment of such cases.

THE USE OF COCAINE IN CIRCUMCISION.

Dr. A. U. Williams, of Hot Springs, Ark., writes: "In the Medical Record of November 1, 1890, Dr. J. B. Bissell presents some objections to the injection of cocaine for circumcision. I agree with the doctor entirely. There are even more objections than he urges to the injection method of using the cocaine, all of which can be obviated by the plan which I have pursued for the last two years. I place the clamp on the prepuce, make my first cut and then pour on the cocaine freely, allowing plenty of time for the anæsthetic effect. The cocaine stops all pain at once, thus applied; there is no œdema to interfere with the lines of incision, and not so much danger of absorption."

Uterine Hernia through the Cicatrix of a Cæsarean Section.—Dr. Sparling reports the case of a woman, thirty years of age, who was suffering from hernia of the uterus through the cicatrix of a Cæsarean section. The woman was seven months pregnant, and her labor had commenced; she was delivered of a dead child, the head having been pulled off the body by the obstetrician's efforts.—*The Montreal Medical Journal.*

Progress of Medical Science.

The Physiological Action of Kava-Kava.—From a study of this subject Dr. Cerua is led to adopt the following conclusions: 1. Kava-kava produces general anæsthesia, and is especially a powerful local anæsthetic. 2. The drug diminishes, and finally destroys, the function of the afferent nerves, by affecting their peripheral ends. 3. Kava-kava diminishes, and eventually abolishes, reflex action, by influencing the spinal cord, and probably also the sensory nerves. 4. The paralysis produced by kava-kava is of a spinal origin, and is due to an action upon the cord. 5. Kava kava, while increasing the force of the heart, diminishes the number of pulsations, by stimulating the cardio-inhibitory centres and ganglia, chiefly the former. 6. The drug lowers arterial pressure through an action upon the vagi. It afterward elevates it, however, especially after previous division of the pneumogastrics, by a direct action on the heart. 7. Kava kava at first stimulates, afterward depresses, and finally paralyzes, the respiration. The primary stimulation is due to excitation of the pulmonary peripheries of the vagi; the latter effect to an influence exercised on the respiratory centres of the medulla oblongata. 8. Kava-kava, in small doses, increases slightly, and in large quantities diminishes, the bodily temperature. 9. The drug increases notably the salivary secretion.—*The Therapeutic Gazette.*

The Brains of Feeble-minded Children.—The *Alienist and Neurologist* for October, 1890, contains Dr. A. W. Wilmarth's report on the examination of one hundred brains of feeble-minded children. The cases are thus summarized: Sclerosis (with atrophy), 12; sclerosis tubereuse, 6; diffuse sclerotic change. 7; degenerative changes in vessels, ganglionic cells, or medullary substance, not constituting true sclerosis, 15; hydrocephalic, 5; general cerebral atrophy, 2; non-development in various forms, 16; infantile hemorrhage, 1; extensive adhesion of membranes from old meningitis, 3; angiomatous condition of cerebral vessels (with degenerative changes), 1; glioma (with sclerosis), 1; porencephalous (with non-development), 1. Of 31 cases where actual disease or imperfect development of brain proper was not demonstrated, there was hypertrophy of the skull, 6; acute softening (recent), 2; demi-microcephalic, 2; when the brain was above usual weight, but the convolutions large and very simple in their arrangement, 2. Actual cerebral disease existed in a comparatively large number of cases, in direct contrast with the relatively small number of instances where imperfect development seems to have been the causative agent of mental defect. Children inheriting inactive brains from parents below the usual average of intelligence, without history of infantile disease or epilepsy, seem the most promising of general and permanent improvement.

Sterilization of Rubber Catheters.—Dr. Alepy describes a method of effecting the sterilization of these instruments, which possesses, he asserts, the merit of being very effective, easy to carry out, and harmless to the instruments. After drawing attention to the effects of various antiseptics, such as carbolic acid, sublimate, etc., and heat as ordinarily applied, he goes on to describe his own plan, which practically consists in wrapping up the instruments, not more than three or four in a packet, in ordinary blotting-paper, the ends of which are just twisted up. These packets are then placed in glass tubes, the mouths of which are sealed with a plug of cotton wool. The glass tubes are exposed for half an hour to ordinary steam, that is, to a temperature of 212° F. The packets of blotting-paper are then removed, and kept in a drawer or box till they are required for use. They remain sterilized for any length of time provided the paper is not opened, as is shown by the fact that they are incapable of infecting either sterilized bouillon or sterilized urine. —*Annales des Maladies des Organes Génito-urinaires.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 4, 1891.

MORBID FEARS AND ALLIED DISORDERS.

IN nervous disease it is not women alone who are capable of fears and subject to fears. Neurasthenics of either sex often become martyrs to dread and apprehension, quite at variance with the serene courage of their normal mental constitution. With every new discovery in science, and with every new convenience, a morbid fear may be developed. In England there is already a horse-car phobia, and the telephone promises to mark some victims for its own. Lack of exciting cause is not a reason why fear of high buildings is as yet non-universal in American cities. Agoraphobia in a woman, the first clinical case in nine years, seemed to Dr. C. W. Suckling, of London, sufficiently rare and interesting to form the basis of a paper that appeared in a recent issue of the *American Journal of the Medical Sciences*, this paper treating of pathophobias and their significance. These morbid states, the author cited looks upon as conditions of partial emotional insanity, similar to minor degrees of *folie de doute*. Neurasthenia, according to Kovalensky, may reasonably be considered the soil from which spring degenerative psychoses or neuroses, the unstable condition of the nervous system being inherited or acquired. The children of persons in whom nerve-force is defective present organic modifications of the nervous mechanism that dispose to these degenerative psychoses and neuroses. Of the first, idiocy is an example; and of the second, neurasthenia, hysteria, and insanity. Beard calls neurasthenia the "American disease," but Dr Kovalensky thinks it might more correctly be named the Russian disease. At all events, it is no respecter of persons or governments, and continues to manifest itself by various expressions of unpleasantness, of which morbid fears are not the least.

The essential feature of agoraphobia, one of the most important of the morbid fears, is an abnormal dread of an open space. Perfectly well in his own house, the patient experiences great fright on attempting to go across the street, or into an open field, and has to run to the shelter of some wall, or he may fall down from weakness that is augmented by violent palpitation and a dreadful feeling of oppression about the heart. As a rule, there is no vertigo, confusion of mind, or loss of consciousness, though pallor and profuse perspiration are usually present. Special senses are for the most part unaffected. The condition may be gradual or sudden in its onset, the patient realizing thoroughly the folly of groundless fears that he has no power to overcome. Will is in abeyance and subservient to violent emotional disturbance. The most trivial circumstances may bring relief, as walking behind a cart, or the presence of a child following the sufferer. It is possible to cross a ploughed field alone, but open meadow lands are as terrifying as undiscovered countries. Home banishes the active symptoms, though a sense of exhaustion remains. In severe forms, agoraphobia renders its unhappy victim a complete prisoner. This state of mind, which is essentially neuropathic, and not hysterical, may last a lifetime, may last months, years, and then disappear, or be followed by definite symptoms of insanity.

Environment as a factor in the production of morbid fears and mental depression, Dr. Suckling thinks of an importance not always sufficiently realized. Small, stuffy, and uninteresting rooms, dingy quarters, and dark houses, exert a most pernicious influence upon mental and physical health. A patient afflicted with mental depression and suicidal tendency was found to live at his place of business, cramped and restricted in every way, where he worked about sixteen hours out of the twenty-four. Lodging out of town, riding horseback to and from business, and diminishing working hours to eight, banished a mental state that might otherwise have resulted in suicide or insanity. From the foregoing, lessons of moment may be learned. Voiceless surroundings are living teachers, always taking part in the education of man on his way through the world. The true instinct of noble things, the pure desires of healthful aspiration, take mankind out of doors, for it is nature who never did betray the heart that loved her. Over-strained by the fret and noise of large cities, with brains and spinal cords jarred by continued treading over stone and brick on an almost uninterrupted level, without wide range for the eye, and with no possible escape from the monotony of monochrome streets, it becomes the American town-dweller's imperative duty to organize family flights into green fields and pastures new, as many times a year as circumstances will allow. The summer exodus is not enough. Why not adopt a sort of bank holiday for the preservation of family health, and arrange that each member of a household shall have an outing of two or three days four times a year? The use of such restoratives as earth, air, sea, and sky at stated intervals, might prove the wisest kind of economy. Therapeutically as well as spiritually speaking, to lift tired eyes unto the everlasting hills brings strength, and the health that is a saving grace. Of course, in all conditions of pathophobia and allied disorders, the cause must be sought for and removed, and the excellences of valerianate of zinc, the hypophosphites, iron, quinine, and phosphorus, ever borne in mind and thoroughly appreciated. But over and above all this rises the first duty of the physician. which is to break up the tiresome aspects into new forms, and thus liberate the victim of pathophobia from the evil enchantment of adverse surroundings.

THE COLOR-CURE OF CANCER.

THE idea has come into the mind of more than one worker in pathology and the art of healing, that the dye

which stains so beautifully pathogenic microbes and the cells and nuclei of diseased tissue outside of the body might be turned to good account in treatment. In theory the idea is excellent. If a staining fluid will attack bacilli in living tissue and render them incapable of making further injury, or by penetrating to the nuclei of pathological cells cause these cells to cease their multiplication, we have at once a treatment which strikes in a most scientific manner at the very root of the evil. Sad as it is to make the admission, theory and practice are twins which are no more alike than though they were distant relatives.

Professor von Mosetig, of Vienna, conceived the idea of staining the cell nuclei of inoperable neoplasms, and thus leading to arrest of development, or possibly to necrobiosis. Methyl-violet or pyoktanin is the coloring agent employed, and injections are made with solutions of from one in two hundred to one in five hundred.

The results, so far as recorded in the original communication, published in the *Wiener Mediz. Presse*, No. 6, do not show any cures as yet, but a number of extensive malignant tumors have been much reduced in size, and improvement has been marked. In a subsequent communication to the Vienna Society of Physicians Mosetig reports upon sixteen further cases of carcinoma and sarcoma treated by his method. A solution of one to five hundred has been found sufficient; but he advises that it be filtered through heated asbestos, and the injections made in a concentric manner from the healthy surrounding tissues. From three to six grams can be used at one sitting.

No bad effects have been observed from parenchymatous injections even when made in parts richly supplied with blood-vessels, and Ehrlich has injected methyl violet into the blood-vessels of rabbits without injury. The effects are said to be produced by softening, fatty metamorphosis, and resorption, in non ulcerating growths, where the skin is intact. Professor Billroth has employed the method in some thirty cases. In three instances of non-ulcerating sarcoma the softening process was followed by ulceration, and this was looked upon as an indication of injurious effect. There was no evidence of resorption.

In carcinoma no beneficial results were obtained. According to Billroth the effects are due simply to the swelling-up properties of the injected water, and he has ordered at his clinic that the injections shall be interrupted as soon as softening is noted, and only begun again if shrinking takes place. In this way, however, treatment is rendered slow, and, in the meantime, the malignant tumors grow rapidly.

It would appear from reports already published in the RECORD that the method is meeting with some favor here, and as it is being tried in several quarters, we shall hope soon to present to our readers something more definite regarding it.

THE OFFICIAL REPORT ON THE USE OF TUBERCULIN.

AN official report has been issued by the German Government giving the results of the use of tuberculin in all the Prussian Universities. The report makes a ponderous volume of 900 pages, and contains the results of treatment, by over sixty physicians, of 1,769 cases.

The diseases treated include tuberculosis in all its forms. The number of deaths occurring during the treatment was only fifty five, and these were chiefly of persons suffering from advanced phthisis. In early phthisis there was not a single death. Among the joint cases there were six deaths.

The number of cures, however, is also very small, being but thirteen among patients with internal tuberculosis, and fifteen among those with joint tuberculosis and lupus.

There were, however, among 951 cases of phthisis, 171 cases markedly improved, 194 slightly improved, and 586 not improved.

Among 683 cases of joint tuberculosis and lupus there were 148 considerably improved, 237 improved, and 298 not improved.

Even allowing for insufficient lapse of time, and the necessary existence of many severe and ill-suited cases the results are most discouraging. Among the seventeen hundred cases, one half were not improved at all. Plainly tuberculin is very far from being the specific from which so much was hoped.

THE GRIP AGAIN.

THERE can be no doubt that the country is suffering from a slight recrudescence of the grip. The term "slight" applies to this city and to most parts of the country. In Chicago and in parts of the West and South, however, it seems as active as it was a year ago. The warm weather is approaching, however, and it is not likely that we shall have a severe epidemic.

LIEBREICH'S TREATMENT OF TUBERCULOSIS.

WE are inclined to take the statement of Professor Liebreich regarding the value of his new method of treating tuberculosis with a great deal of reserve. Professor Liebreich is no doubt a learned man, and he gave us chloral, for which it may be questioned whether humanity should be thankful. His later therapeutic contributions have been of much more questionable value. Lanolin, though widely advertised is not very highly esteemed, while Liebreich's attempts to find a better anæsthetic than cocaine were signal failures.

His present remedy for tuberculosis is cantharidate of potash, and his theory of its action is that it produces a transudation of serum, especially in the capillaries of diseased localities. The transudation of serum may have therapeutical effects in two ways: (1) by nourishing the cells and bringing back to their normal condition badly nourished cells; and (2) by the disinfecting action of the serum at the affected spot.

Professor Liebreich says: "If it can be proved that in cantharidin we possess a means of producing an increased secretion of serum at any one spot, we may succeed in concentrating at this spot efficacious substances, which, under ordinary circumstances do not easily find their way there. We know substances that circulate in, and are decomposed by, the blood, but which only with difficulty pass through the capillaries. But if we know that

at an affected spot the exudation from the capillaries is facilitated, we can imagine that a larger quantity of an efficacious substance may find its way to this spot, thus strengthening the otherwise feeble disinfecting power of the serum. It seems to be not unlikely that such a combination of two remedies might possibly lead to a new therapeutic method. As regards practical application, special attention should be paid to the kidneys. It is clear that this treatment should not be applied where there is disease of the kidneys. I should advise doses of one decimilligramme to begin with, followed by an experimental increase to two decimilligrammes. It is as well to let a day elapse between the injections."

Cases have been shown in which the treatment has caused "wonderful improvement" And it is but just to say that Virchow, who has been very systematically inserting his scalpel beneath the fifth rib of "tuberculin," has spoken favorably of the "canthardate."

Perhaps after all the bacillus will have to bow down to the blister.

THE NAVAL MEDICAL SERVICE.

Mr. Tracy, Secretary of the Navy, is evidently no friend of the medical profession, nor is he very keen for the improvement of the *personnel* of the service, if one may judge from the following Washington despatch printed in the New York *Times*. The writer says:

"The medical corps of the Navy is still experiencing considerable difficulty in filling vacancies in the grade of assistant surgeon. Several candidates have recently been examined by the New York Board, but none was successful. The San Francisco Board has been dissolved because no candidates presented themselves. The medical colleges are now being canvassed by tempting circulars sent out by the Navy Department. The reluctance felt by students toward entering this branch of the Government service is obvious. Until Congress has increased the pay and conditions aboard ship of assistant surgeons, medical officers say that it will be impossible to keep the corps recruited to its full quota unless the standard of examination is reduced. This Secretary Tracy has absolutely refused to do."

The Naval Department is expending enormous sums in the building of ships; but, after all, these new monsters of the sea cannot be efficiently utilized without a high class of officers and men. Money expended in promoting this end would be wisely spent, and it is difficult to understand why, when millions are spent on experimental ships and guns, a few thousands cannot be used for raising the standard of the medical service to that of the army. As it is now, it looks as though it was involuntarily boycotted.

"TRACHEAL TUGGING."

Dr. R. L. Macdonnell calls attention (*The Lancet*, March 7, 1891) to a symptom designated as "tracheal tugging" which he thinks is pathognomonic of aneurism of the arch of the aorta. The symptom has been observed by Dr. George Ross, of Montreal, and is described by him in Wood's "Reference Handbook of the Medical Sciences." Dr. Ross there says: "Another physical sign of very great diagnostic importance, and which is also to be obtained by the educated sense of touch, is what is now known under the term 'tracheal tugging.' It is but quite lately that attention has been directed to this method of examination, and it is only now that its value has been realized. If a deep-seated aneurism be present which impinges at all upon the trachea or one of its principal divisions, then a very distinct and unmistakable tugging downward will be felt with each systole of the heart. When the heart is acting strongly, or when aortic incompetence is present, considerable rhythmical pulsation may be communicated to the fingers from the adjacent carotids, but with a little care this cannot be mistaken for the tugging directly downward above described. I have observed a number of cases of thoracic aneurism, cardiac and other thoracic diseases, with reference to this sign, and I have never observed it produced by any other condition but aneurism." The symptom was first described, however, by Surgeon-Major W. S. Oliver in 1878, and the method of examination given by him is as follows:

"Place the patient in the erect position, and direct him to close his mouth and elevate his chin to the fullest extent, then grasp the cricoid cartilage between the finger and thumb, and use gentle upward pressure on it, when, if dilatation or aneurism exist, the pulsation of the aorta will be distinctly felt transmitted through the trachea to the hand. The act of examination will increase laryngeal distress should this accompany the disease."

According to Dr. Macdonnell, this symptom, though one of positive value, has never been studied or looked for by hospital physicians, with a very few exceptions. He collects the histories of twenty-five cases occurring in the Montreal General Hospital, and finds that in seventeen the symptom was present.

A THERAPEUTIC EVOLUTION.

The whirligig of time brings its changes in medicine as in other departments of knowledge. Silent and slow, but sure and steady, is the evolution of therapeutics from the mystical and coarsely empirical to logical and rational methods.

The use and abuse of quinine is an illustration of the iconoclasm which in this enlightened era beats relentlessly upon hoary tradition, or more recent opinions, if these cannot meet it by physiological, pathological, or other truly scientific evidence.

The malarial idea which has prevailed so long in this city, despite the protests of men whose lives had been spent in malarial countries, has just received from the able paper of Dr. W. B. James, and the discussion following it, a report of which appeared in our last issue, a *coup de grâce* from which it is not like to recover.

The extent to which malaria was accepted as an almost universal pathological factor in this city was graphically delineated in a paper which appeared in our issue of November 10, 1883, by Dr. Simon Baruch. The author, who had removed to this city from a malarial section of the South, was astonished to discover the reputed prevalence of mild, severe, and fatal malarial fevers in midwinter in this Northern city. He claimed that New York does not furnish the combination of elements necessary for the production of true malarial fevers, except to a limited extent, and in circumscribed localities; that it is

utterly impossible for five hundred and eighty-six deaths (as recorded by the Board of Health) from malarial diseases to occur from January to April, with an average temperature of 33.98° F. He cited clinical evidence, the accepted favorable prognosis of malarial fever in temperate climates, and the report of Dr. Russel to prove that the errors of diagnosis of malaria have conferred upon New York a reputation which is as unenviable as it is unmerited.

These arguments seem to have remained unanswered, save by the continued appearance of malarial diseases as causes of death in this city. In 1888 there were reported 842 deaths, in 1889, 742 deaths from malarial diseases, the largest proportion of which seem to have occurred during the winter months, the smallest during the summer.

Dr. Baruch has long ago shown the fallacy, indeed the absurdity, of such statistics, inasmuch as even in tropical climates fatal malarial disease occurs chiefly, if not entirely, during the summer months, and in sub-tropical countries they cease after frost.

Dr. James' conclusion, that "in this city malarial poison is indigenous either to a very slight degree or not at all," confirms most positively by microscopic and clinical evidence the conclusions arrived at by Dr. Baruch regarding the erroneousness of the usual diagnosis of malaria and the abuse of quinine in this city, and presumably elsewhere.

Pathological and clinical evidence is also furnished by the discussion of Dr. James' paper.

The abuse of quinine is fortunately not prejudicial to life; but the groping for diagnosis is decidedly prejudicial to patient and doctor. If the recent discussion will serve to call a halt in both directions, it will subserve a useful purpose.

MALTHUSIANISM.

A CORRESPONDENT, referring to an item in the MEDICAL RECORD regarding the Malthusian ideal of marriage, asks us to tell him what it all means. The Rev. Mr. Malthus was an English gentleman who in the beginning of this century attempted to show that the population of the world doubled every twenty-five years, or in about a geometrical ratio; while the means of subsistence increased in an arithmetical ratio. Hence he predicted eventual starvation for the human race unless artificial checks to population were introduced. His advice was "Do not marry until you have a fair prospect of supporting a family," and, as a matter of fact, his ideal of marriage was simply one in which the head of the family could support his prospective children. Practically, however, a childless marriage is often referred to as one of a Malthusian character, since it is one that checks instead of increases the population.

The Price of Quinine has declined to such an extent that manufacturers have organized a gigantic trust to advance it. One German firm has refused to co-operate, and until it is crushed from existence there will be strife as bitter as the drug. The price will remain low until the refractory firm is disposed of, and then fever and chills will be a luxury.

News of the Week.

Golden Jubilee of the Missouri Medical College.—The Alumni Association of the Missouri Medical College gave a banquet, on March 31st, in commemoration of the Semi-Centennial of their Alma Mater, at the Lindell Hotel, St. Louis.

Tennessee State Medical Society.—The Fifty-eighth Annual Meeting of the Tennessee State Medical Society will be held in the public hall of Watkins Institute, corner of Church and High Streets, Nashville, Tenn., April 14, 15, and 16, 1891.

Iowa State Medical Society.—The Fortieth Annual Session will be held at Waterloo, Ia., Wednesday, Thursday, and Friday, April, 15th, 16th, and 17th.

Dr. William H. Baker, Professor of Gynecology in Harvard School of Medicine, while on a Western trip, recently, was tendered a very pleasant dinner at Cincinnati by Dr. T. A. Reamy, Professor of Clinical Gynecology in the Medical College of Ohio. The prominent men of the profession of Cincinnati were well represented at the feast.

Commencements in Cincinnati have resulted as follows: Medical College of Ohio, 94; Ohio College of Dental Surgery, 75; Cincinnati College of Pharmacy, 29; Miami Medical College, 27; Cincinnati College of Medicine and Surgery, 25; Pulte College, 29; and Woman's College, 2.

The Cincinnati Academy of Medicine elected the following officers: *President*, Dr. Giles S. Mitchell; *Vice-Presidents*, Drs. G. W. Ryan, and T. A. Reamy; *Secretaries*, Drs. J. M. French and E. S. McKee; *Treasurer*, Dr. George E Jones.

The Mississippi Valley Medical Association will hold its Seventeenth Annual Session at St. Louis, Wednesday, Thursday, and Friday, October 14, 15, and 16, 1891.

American Academy of Medicine.—The Sixteenth Annual Meeting of the American Academy of Medicine will be held at Washington, D.C., May 2d and 4th, opening at 3 P.M. May 2d. As it will be just previous to the sessions of the American Medical Association, members will be able to attend both meetings.

A New Medical College in North Carolina.—At a meeting of a number of prominent physicians of North Carolina, held at Durham, in that State, upon March 18th, to consider the question of establishing a medical college in connection with Trinity College, the preliminary arrangements were perfected leading to the organization of a school of high standard, thorough equipment, and three years' course.

Leprosy in British Columbia.—The Canadian Department of Agriculture has lately received word that leprosy in its worst form exists in British Columbia. Six Chinamen affected with the dire disease have been isolated at Victoria. They were discovered in a rookery in the Chinese quarter, where they had been secreted by their countrymen. The department will send a physician to Victoria for the purpose of ascertaining the extent of the disease on the Pacific coast.

An Act to Regulate the Practice of Medicine in the State of Rhode Island and to Provide for a State Board of Medicine, has been introduced into the Assembly. It is somewhat like the New York law, except that the Board of Medicine does not examine, but simply audits and registers the diplomas.

Dr. Charles T. Parkes, Treasurer of Rush Medical College, and one of the leading surgeons of the West, died on March 28th, of pneumonia. Dr. Parkes had made particularly valuable and original contributions to abdominal surgery.

A Successful Case of Removal of a Brain Tumor is reported by Dr. McCall Anderson and Dr. George Buchanan.

German Universities and Medical Women.—In the German Reichstag, on March 11th, Herr Schröder urged, in the course of a discussion in favor of the admission of women to the liberal professions, that it was the duty of the Government to pave the way for women to practise medicine. Dr. Orterer opposed this view. The House declared against the petition.

Hypnotism and the Practice of Medicine.—The Conference of Paris Advocates have recently discussed the following question: Should a person who, not being a member of the medical profession, performs hypnotic experiments on another, be prosecuted for illegal practice of medicine? After full debate the question was decided in the affirmative. This may give rise to some interesting discussions in this country. Will our County Medical Society have authority to stop the performances of professional mesmerizers?

A Large Fee.—Professor Grube, of Charkow, has received a fee of 5,000 roubles (nearly £800), besides travelling expenses, for an operation which he performed on a rich fishmonger of Astrakhan. Dr. Grube was in Astrakhan one day and one night.

A Medical Countess.—The Countess Wanda von Szeawinska has just taken the degree of doctor of medicine in the University of Geneva. The learned lady is said to intend to practise her profession in her native country, Poland.

The Lady and the Sign.—Some unusual incidents in connection with doctors' signs are reported from Chicago by the *North American Practitioner*: "A physician of the feminine gender caused her sign to be stolen lately and then offered a reward of $500 through the daily press for its return. We remember this sign as being worth about $1.74, hence there must be $498.26 of advertising in the affair."

Royal College of Physicians of Edinburgh.—In terms of the bequest made to the Royal College of Physicians of Edinburgh by the late Dr. John Parkin, Fellow of the College, a prize is hereby offered for the best essay "On the Curative Effects of Carbonic Acid Gas, or other Forms of Carbon, in Cholera, the Different Forms of Fever, and other Diseases." The prize is of the value of one hundred pounds sterling, and is open to competitors of all nations. Essays intended for competition, which must be written in the English language, to be received by the Secretary not later than December 31, 1892. Each essay must bear a motto, and be accompanied by a sealed envelope bearing the same motto outside and the author's name inside. The successful candidate must publish, at his own expense, and present a printed copy of it to the College within the space of three months after the adjudication of the prize. In name and by authority of the Council of the College. G. A. Gibson, M.D., *Secretary*. March 9, 1891.

Free Patients Scarce.—Even the dispensaries are beginning to complain of scarcity of patients. The following is a clipping from the *Louisville Courier-Journal*. "The students at some of the medical colleges are complaining about the poor attendance in the free dispensaries and morning clinics, and especially in the dental department of the Hospital College of Medicine. So far there has not been a patient at the dispensary this session. Dr. John Blair, who is in charge of the dental infirmary at the college, said that in other cities there was the greatest demand on the part of the poorer classes for this free treatment. 'The public here,' he said, 'have apparently not the same confidence in our institutions as they have at the North.' There is no reason for this lack of confidence, for the patients who go to an infirmary receive as good treatment as they can in private parlors. We will take as many patients as we can get, and in order to accommodate them we have had the infirmary enlarged and a number of improvements made. We would like to have as much work as we can do.'"

[Why not offer premiums, employ dispensary "feeders," or take to the fence with posters?—Ed.]

"Tr. Opii Pulv."—A medical case in the Chicago courts has recently attracted considerable attention. It appears that some two years ago a physician, in prescribing for an infant three months of age, suffering from otitis wrote, "Tr. opii pulv.," which the druggist interpreted—either rightly or wrongly—laudanum, and filled the prescription accordingly, notwithstanding that the dose called for was toxic, as was proved by the death of the child some few hours thereafter from symptoms of opium-poisoning. The physician afterward recognized and admitted his part of the error, and consented to arbitration touching the question of damages. Three prominent clergymen were therefore selected to whom the matter was referred, but their verdict being unsatisfactory a suit at law resulted. The evidence brought out the fact that the word "Baby" had been written by the physician before the surname of the patient, and it was argued from this that the druggist should have paid more heed to the opium ingredient. Testimony further showed from representative physicians and druggists that technically there was no such thing as "Tr. opii pulv.;" that while it would more readily be interpreted as laudanum, yet the peculiarity of the term should have attracted immediate attention to the original error. The defence was that the physician was not wholly culpable, even admitting that an error in expression had been made; and, furthermore that there was no criminal neglect, and that no financial value could be placed upon the life of the child. A decision was returned of $500 against the physician. A motion has been made for a new trial, and the outcome will be watched with interest.

Stated Meeting, March 16, 1891.

SAMUEL B. W. McLEOD, M.D., PRESIDENT, IN THE CHAIR.

Treatment of the Various Forms of Pulmonary Consumption with Vaccine Lymph.—DR. J. HILGARD TYNDALE read the paper and presented nine patients illustrating the results of the treatment. It was of great importance to make an exact diagnosis of both the local and the general condition of the patient. An active destructive process, either local or general, was precipitated by the invasion of the tubercle bacillus. We should find out to what extent the lung capacity had been encroached upon, either by infiltration, shrinkage, or excavation, also by the influence of pleuritic adhesions. Also learn whether there was sufficient lung substance left to carry on oxygenation of the blood. The likelihood of immediate or remote invasion by the tubercle bacillus was the most important point. The fat and blood formation, the general nutrition of the patient, next claimed attention. Having a clear picture of the local destructive process and of the general condition before him, the physician could decide intelligently upon a course of treatment. There were four kinds of patients: 1, Those in whom the general condition was good, the local lesion limited and just beginning to be active; 2, those in whom the general condition was below par and the local change not great; 3, those in whom constitutional impairment was grave and local destruction advanced and disposed to be active; 4, those in whom the local lesion was extensive but not active, and the general condition reasonably good. But the maxim was, that each case must be a law unto itself.

The author believed that those who were seeking a remedy by injecting some animal virus or chemical substance of intense toxical effect were on the right track. The substance which he had selected for inoculation was pure vaccine lymph from the cow. It came in capillary tubes, each one containing about two drops of the lymph, while as a solvent he used fifteen drops of pure distilled water and one drop of glycerine. He had made the injections subcutaneously near the seat of the lesion, using an ordinary hypodermic syringe. At the third and fourth injections he had frequently used two tubes. One injection in six or seven days was often enough. When the bacilli disappeared from the sputa, the expectoration scarce and of mucous character, it was not necessary to inject oftener than once in two, three, or four weeks. There was no active reaction. The temperature might rise from 100° F. to 102° F. within twenty-four hours, and sometimes there was frontal headache.

Benefit had shown itself on the fever, the expectoration, the night-sweats, appetite, muscular strength, diarrhœa, cough as a peripheral irritation, and consequently on the loss of sleep, on the feebleness and rapidity of the heart's action, on fluor albus in women; also in changing or clearing up the local signs. In some cases the benefit was apparent almost from the beginning, in others it showed itself gradually. Other measures had not been neglected, but usually had been put off until benefit from the lymph had become manifest. They consisted in tonics, lung gymnastics, and removal of obstructions to respiration in the upper air-passages. Symptomatic treatment should be abandoned except when urgently called for to give temporary relief. He laid stress on the fact that the method was successful in treating connective-tissue processes, equally so in clearing up cheesy infiltrations even though the normal structure could not be restored. As to the tubercle bacillus, he said we could successfully eliminate local tuberculosis, but thus far the line had been drawn at general tuberculosis, especially of the lung. It was the author's belief that more than one animal virus or chemical intoxicant would be found which would accomplish the same object.

The nine patients presented represented different forms or stages of pulmonary consumption. In the first case the young man's father had died of phthisis. The general condition at the time of coming under treatment had been fair, the local change not very great, there being infiltration at both apices to the upper border of the second rib, manifested by diminished vesicular inspiration, tubular respiration at the right apex, broncho-vesicular at the left, which under treatment had entirely disappeared, while the general condition had considerably improved. In the second case, also that of a young man, the local condition was limited while the general condition was exceedingly bad; constant temperature of 100° F. Under the injections the local process had disappeared, the temperature had become normal, the general condition much improved. In the third case the general condition was bad, there was pulmonary infiltration on both sides at the apex, small cavity in the right apex, patient much emaciated, very pale; temperature ranged from 100° F. to 101° F.; the sputa showed a number of bacilli. Under treatment the infiltration had disappeared, where the small cavity had been there was then insufficient vesicular breathing, no dulness, the general condition good. The fourth case, also a young man, temperature at all times ranged from 102° F. to 102.5° F.; muscular strength nil, cavity in the left apex, infiltration in the right apex, emaciation very great. Since the injections had been made he had regained muscular strength, was in good general condition, over both apices there was diminished vesicular breathing, but no râles, no sputa, cough from irritation in the upper air-passages had become better. The next case, in a young man, was one of hemorrhagic tendency. His mother had died of phthisis, aged thirty-six. When he first saw the patient he had had three hemorrhages, one afterward; was in a weak condition; temperature then at 104° F. The cavity together with the infiltration had extended down to the fourth rib. The temperature had become normal under treatment, the general condition good, no cough, but there was still tubular respiration in the right lung, vesicular breathing around, a very slight dry crackle at the edge where adhesions had taken place. The other cases presented, two being women, were equally typical with regard to the local and general condition and the benefit produced.

During the course of the discussion by Drs. Kretzschmar, J. Balke White, Paul Gibier, Truax, and Agramonte, the author stated that he had treated altogether by this method twenty-three cases, and the results in the others were very similar to those in the patients presented; that in the beginning he used the virus by scraping, as in ordinary vaccination against small-pox, and in some of those cases spots formed, but no abscess or spot formed when injections were resorted to; that the bacillus tuberculosis had been present in the sputa of nearly all the patients, that it disappeared in nearly all, or the expectoration ceased. In some the treatment was begun over five months ago. Dr. Agramonte remarked that not one of the nine patients had coughed or expectorated during the half hour they were in the room, yet all had a phthisical appearance. All expressed astonishment at the results described by the author, and hoped they might be confirmed by future experience.

Sterilized Milk.—DR. E. F. BRUSH read the paper. Heat, he said was originally applied to food to make it more digestible. At present there was an additional reason, to avoid real or imaginary danger from germs. The general warfare against all germs now prevailing, leading as it did to the sterilization of food, might prove dangerous. It was true that perfect sterilization applied to food meant the death of bacilli, but whether perfectly dead food exclusively fed to the infant was best, might be questioned. All wild animals had their natural food. Man imagined that babes could be nourished on artificial preparations alone. The statistics, however, showed how

poorly this method succeeded. All the teachings of nature seemed to point to vitality as a prime necessity in food. But contrary to this law, the bacteriologist sought to thoroughly devitalize it The milk consumed by older persons constituted only a part of their food, and might be devitalized by heat without danger to health where vegetables or other food not devitalized constituted a part of the diet. But in the case of the infant, which got nothing else except cow's milk, he believed the uncooked milk from healthy dairy cattle was far better than boiled milk. It was more nourishing, more completely fulfilled the demands of the animal economy. He did not deny the danger of using milk from diseased cows without sterilization, but fresh uncooked milk from healthy cows was necessary when the child had no other food. The dairy cow should not be a breeding animal; she should be spayed.

Dr. Gibier made some remarks on the danger of using unsterilized milk.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 28, 1891.

H. M. Biggs, M.D., President, in the Chair.

Pernicious Anæmia in a Child Two Years of Age (Immense Spleen, Fatty Heart, Slight Cirrhosis of the Liver).—Dr. L. Emmet Holt presented specimens from such a case, accompanied by the following history: The child was twenty-five months of age, and had been under observation at the Babies' Hospital for the last three months of its life. It had previously lived in a malarial district, but without any distinct malarial attacks. It was admitted for a severe ulcerative stomatitis and anæmia. It had had several attacks of bronchitis, and one attack of broncho-pneumonia in infancy.

On admission the child's general condition was poor; the spleen was enlarged, being at that time one and a half inch below the border of the ribs; the liver one and a half inch below the free border of the ribs, and its border normal by percussion. There was no fluid in the abdominal cavity, but the abdomen was large. There was no enlargement of the superficial lymphatic glands. The child improved steadily under treatment for six weeks, and at the end of this time the mouth was almost well, she had gained in weight, and the anæmia was less marked. For the last six weeks the course of the case had been slowly but steadily downward—increasing anæmia, occasional hemorrhages from the nose, and exacerbations in the stomatitis, the latter finally extending until it involved the alveolar spaces and caused the loss of two or three teeth, and finally a sequestrum, three-fourths of an inch long, was removed from the jaw. Two weeks before that the spleen had enlarged so that it reached four inches below the ribs, and its internal border was one and a half inch to the left of the umbilicus, and in the axillary line half an inch above the crest of the ilium. Its inner border was enlarged, so that it reached two inches below the border of the ribs in the mammary line, and two and a half inches in the median line, and presented a smooth outline. There was no jaundice; there was no fluid in the abdominal cavity, and the anæmia at this time was extreme. A loud hæmic murmur was heard at the base of the heart, and small, punctate hemorrhages were present over the abdomen and extremities. Examination of the blood showed a marked increase in the white corpuscles, but not enough to warrant a diagnosis of leucocythemia—the proportion was probably not above one to fifty. The red globules were irregular in size and shape, and no pigment was observed. For the last two weeks a marked febrile movement was present, the temperature ranging from 99° F. to 103° F. Quinine was given in large doses, but had very little effect upon the temperature. The size of the spleen was slightly reduced under the influence of the quinine. There was no jaundice at any time, no emaciation, but diarrhœa was present at short intervals during the whole illness, but it was never continuous. There were no hemorrhages from the intestine at any time, and the urine contained albumin only for the last two days, and no blood was found under the microscope. There were no large hemorrhages, either subcutaneous or from the mucous membranes. During the last four or five days of life signs of broncho-pneumonia developed. There were no cerebral symptoms. There was slight œdema of the feet noticed during the last week only.

At the autopsy, which was made nine hours after death, the brain was negative. The skull was thickened and very vascular, and there was a pachymeningitis interna over the whole convexity, the pseudo-membrane being half a line in thickness. Minute hemorrhages were found scattered pretty thoroughly in this membrane. The sinuses contained soft, dark clots. The lungs were both slightly adherent at their upper portions, and there were evidences of recent broncho-pneumonia in both lungs posteriorly, and of old pneumonia in the right. There was no fluid in the pleural cavity. Sub-pleural ecchymoses were seen everywhere. There were small ecchymoses over the visceral pericardium, but none over the parietal layer. The heart was very pale, and extremely fatty, the striations of fatty degeneration showing typically in the papillary muscles. There were no valvular lesions. The spleen was six inches long, three and a half inches wide, and one and a half inch thick in the thickest part, and weighed five and one-fourth ounces. There were adhesions to the abdominal wall, due to a moderate peri-splenitis; the inner border was notched, the organ firm, and a little darker than normal, and the gross appearance presented nothing positively diagnostic. The liver was about one and a half times the normal size, pale and anæmic; fatty degeneration in the centres of the lobules, and fine grayish striæ at their periphery. The gross appearance was strongly like that of a pig's liver. The organ was not jaundiced. There was no fluid found in the abdominal cavity. The stomach contained a quantity of brownish mucus, and there were a few small ecchymotic spots in the mucous membrane, but evidences visible to the naked eye of acute or chronic gastritis. The upper part of the ileum was moderately congested, but Peyer's patches were not swollen. The colon was normal. The mesenteric glands were slightly enlarged, but not cheesy. The pancreas was normal. The kidneys were slightly enlarged and pale; the markings were only fairly distinct, and there was marked cloudy swelling of their cortices.

Microscopical Examination.—The heart showed well-marked fatty degeneration, and, in addition, there are scattered about between the muscle-fibres small collections of small spheroidal cells. It was not determined whether the cells were contained in a connective-tissue reticulum or not. The liver showed moderate cirrhosis. The connective tissue was especially cellular, and newly formed gall-ducts, as so often occurs in cirrhosis, could be detected. Scattered about, usually between the lobules, were collections of spheroidal cells, presumably hyperplastic lymph nodules of Arnold. The spleen showed a combination of the lesions of congestion with interstitial splenitis. The kidneys showed well-marked parenchymatous degeneration, with proliferation of the endothelium lining the tufts of the glomeruli.

Dr. J. S. Thacher said that he had recently seen at St. Luke's Hospital a case diagnosticated as hypertrophic cirrhosis of the liver, and a perusal of the cases collected by Dr. Howard, in the "Transactions of the Association of American Physicians, for 1887," and of the more recent contribution of Dr. Edwards, in the "Archives of Pediatrics," made it evident that this condition was much more common in children than was generally supposed. There had been a number of such cases reported to the Calcutta Medical Society, in which there was moderate jaundice, little or no ascites, a large, dense liver, and a greatly en-

larged spleen. In one case, in which a post-mortem examination was made, hypertrophic cirrhosis was found, but without the fatty degeneration which is usually a marked feature.

As to the causation of this condition, Italian physicians firmly believed that it was of malarial origin. In the Calcutta cases it was noted that it was not nearly so frequent among children living in the country as in those dwelling in Calcutta.

Dr. Thacher then presented sections from a tumor which had been removed from near the shoulder of a young woman. The tumor was intimately adherent to the upper part of the right clavicle, and the mass which had been sent to him for examination was irregular, and about half the size of the fist. He would like to hear the opinions of the members as to its nature.

Several of those present considered it an adenoma.

Tuberculosis of the Prostate and Seminal Vesicles.—Dr. H. M. Biggs presented a specimen of tuberculosis in which the only lesions in the body were confined to the genital organs. The testicles were tuberculous, and the seminal vesicles extensively involved, while the prostate was converted into a cheesy mass. The bladder was anæmic, apparently as a result of the obstructed circulation due to the prostatic enlargement. The patient, who was a man about sixty years of age, died of acute lobar pneumonia.

The specimen was interesting as a further contribution to the subject of the localization of tuberculous processes, and emphasized what he had said on other occasions about the occurrence of primary tuberculosis in almost any organ of the body. Last November he had presented to the Society a specimen illustrating a tuberculous process limited to the suprarenal capsule, and during the last two years various similar specimens had been presented.

The Society then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE GULSTONIAN LECTURES ON LEAD POISONING AT THE COLLEGE OF PHYSICIANS—DISCUSSION ON ANGINA PECTORIS AT THE MEDICAL SOCIETY OF LONDON — THE PROGNOSIS OF STRUCTURAL DISEASES OF THE HEART —THE GOVERNMENT PROPOSAL TO ABOLISH FACTORY SURGEONS—THE RECONSTITUTION OF THE UNIVERSITY OF LONDON.

London, March 14, 1891.

The subject of the Gulstonian Lectures delivered at the College of Physicians is "Lead-poisoning in its Acute and Chronic Manifestations," and Dr. Thomas Oliver, of Newcastle on-Tyne, has been the lecturer. Referring to the antiquity of lead-poisoning in his first lecture, Dr. Oliver remarked that Galen condemned the use of lead pipes and the Roman architect Vitruvius forbade the use of lead for conducting water, owing to the *ceruse* which it formed being hurtful to the human body. Nicandre had described lead poisoning. The poison, said the lecturer, was introduced into the system through many channels. Those engaged in lead mining never suffered. The danger began with the smelting of the metal; this was a hazardous occupation, and the fumes were injurious, not only to human beings, but to cattle in the neighborhood. The worst types of plumbism were met with among lead workers. The smelter was the first to suffer, and the next danger arose during the conversion of the metal into white lead or carbonate. No known method of procedure was equal to the old Dutch method; this was simple but dangerous. Drinking-water, fermented liquors, hair dyes, false teeth (the plates of which contained lead), and the contamination or food, were then mentioned as sources of lead-poisoning. Dr. Oliver remarked that the *colique sèche* of the French navy was nothing else than lead-poisoning. His own experience had been gained mostly from workers in lead factories. The months of June, July, and August had supplied the largest number of cases in the north of England. It was difficult, he said, to say the age at which plumbism was most apt to occur; children were not exempt, but adults were most exposed to the influence of lead, and therefore suffered most. There was no doubt in his mind that females were more susceptible to plumbism, and this opinion was shown to be correct by the statistics of epidemics; it was, however, at variance with that given by several authors. Lead as a poison struck early at the functions of blood-making and reproduction, producing sterility, liability to abortion, and amenorrhœa or menorrhagia. Alcohol greatly increased the influence of other factors in determining lead poisoning. Once an individual had suffered from lead-poisoning, he was launched upon a morbid stream of life where, under the influence of metabolism making for health, he might recover; on the other hand, if unwilling to abstain from alcohol, and exposing himself again, he floated rapidly down the stream. A further attack after a period of quiescence, and without fresh exposure, was due to the fact that lead was deposited in the system and, under the influence of some particular food, drink, or medicine, was again rendered soluble and circulated afresh in the system, thus poisoning the person with lead absorbed from his own tissues.

In his second lecture, Dr. Oliver remarked that lead might be taken into the system either in a state of solution, of fine subdivision, or dissolved in some volatilized agent, such as turpentine. The one physical sign above all others which indicated that the system was becoming impregnated with lead, and was suffering, was anæmia, which gradually increased and was spoken of as saturnine cachexia. Hæmatosis was interfered with almost from the first day of exposure to lead, and he had never found in a lead worker the normal number of red blood-cells. There was a marked increase in the number of white cells. The physical sign of plumbism which was most looked for and generally met with was the presence of a blue line on the gums, noticed by Burton, but previously described by Tanequerel. It was a valuable sign, but it might be absent, and it generally was when the teeth and gums were perfectly sound and the mouth was kept cleansed. There were two blue lines. One was a delicate line just at the margin of the gum; this was a deposit of lead on, and not in, the gum, and was easily removed by cleansing the teeth and rinsing the mouth. The other, and more characteristic line, was bluish-black, and occurred also at the margin of the gum, where it was not in complete apposition with the teeth; there the gum was frequently ulcerated and irregular in outline. Dr. Oliver said he had seen a blue line appear the day after a large dose of acetate of lead had been taken; it persisted for a few days and then disappeared. It was difficult to say how long the blue line would remain after removal of the individual from the influence of lead. In some of his cases it had disappeared quickly (eight days was the earliest period), but in the severer forms it remained three. or even six, months. He had never succeeded in developing it when absent by giving iodide of potassium, as some authors were said to have done.

Sudden and severe abdominal pain was an early symptom of plumbism; in one of the lecturer's cases it occurred eight days after exposure. There were two kinds of pain: the paroxysmal or acute pain, which was the true lead-colic, and which was generally relieved by pressure; the other was a dull continuous pain, which followed it in the intervals, and this was usually aggravated by pressure. During attacks of colic the pulse was slowed, arterial tension increased, and the renal function almost completely suspended. An early symptom also was an alteration of the menstrual functions. There was often menorrhagia; others suffered from amenorrhœa. Abortion was frequent. The lecturer then discussed the

various forms of lead-paralysis, from the classical wrist-drop to the generalized paralysis in which muscles of legs, back, shoulders, and arms were affected.

The adjourned discussion on "Angina Pectoris" at the Medical Society was brought to a close on Monday evening last, having occupied the society for three meetings. I gave some account of the first evening's discussion in a previous communication. At the second evening of the discussion. Sir Walter Foster, Professor Grainger Stewart, and Professor McVail were the principal speakers. Sir Walter Foster narrated several illustrative cases, and said that in all of them he believed the immediate cause of the heart pang to be distention of the cavities of the heart—either right or left. He held that stretching and not spasm was meant by the "distensio" of Heberden. In all, or nearly all, of the cases he thought there was a degeneration of the myocardium with distention of the cardiac cavities. This view was counter to that of neurosis, but he knew of no direct evidence to support the idea of spasm of the coronary arteries. He preferred to regard angina, not as a disease, but as a mode of death, and as a term under which might be grouped a number of allied conditions having a common pathological basis. A scientific step has been made in treatment when drugs like nitrite of amyl and nitroglycerine were introduced—drugs which counteracted the vascular condition which was the starting-point of the malady.

Professor Grainger Stewart said that cases of angina pectoris grouped themselves into four categories: (1) Simple neuralgia of the heart, which was very amenable to treatment; (2) a condition of angina dependent upon, and associated with, acute or subacute inflammation of the aorta; (3) where angina was associated with fatty, fibrous, or rather degeneration of the cardiac walls, or with changes in the coronary arteries; (4) angina associated with spasm of the arteries and increased tension, there being but little change in the heart. In any of the three last groups the same lesions might exist without pain, so that we had to ask what was the explanation of the pain when it occurred. Was it of muscular or of nervous origin? Professor Stewart said he looked upon it as a pain of nervous rather than of muscular origin, and he pointed out that epileptiform neuralgia was wonderfully like it, coming on in sudden paroxysms, and often ceasing as suddenly, leaving the patient subject to a new attack, being more common in men, and at or after the middle period of life.

Professor McVail observed that the pain might be general or partial, and he mentioned its varying characters. The two previous speakers, he said, had contended that it was not cramp. Was it possible to separate cramp from a neurotic condition? Though it might be done in laboratory work, it was quite impossible to separate them in practice. He himself was quite unable to separate the nerve condition from the muscular condition of the heart, as regarded pain. An ordinary muscular contraction was a pleasurable sensation, as in exercise; but if the contraction were much increased in intensity, as under strong faradism, it then became painful and was a condition of cramp. For his part he upheld the old idea of Heberden, as supported by Latham, that the condition of angina was immediately dependent upon spasm of the heart.

On Monday evening last the discussion was reopened by Dr. Lauder Brunton, who compared the heart to the bladder to explain the pain produced by over distention. Disturbance of their nervous relationship might cause excessive distention or pain in either organ, apart from organic disease, giving rise to spamodic retention or vasomotor angina. But while the spasmodic character of angina pectoris indicated its nervous origin, it was so frequently associated with diseased coronary arteries and fatty heart, that these evidently played a great part in its causation. Angina pectoris might be said to be due neither to high tension alone nor weak heart alone, but to weakness of the heart in relation to the resistance it had to overcome, and it might be brought on either by weakening the heart or increasing the resistance, or both together.

Dr. Mitchell Bruce contended that an attack of angina was determined not so much by the vaso-motor condition as by the relation of the state of the pulse-tension to the state of the heart behind it. It was really a matter of relation between the pressure ahead and the driving-power, and in the great majority of instances it was the fault of the heart and not of the periphery. He thought the term "gouty heart" expressed best the condition most often present.

Dr. De Havilland Hall observed that Dr. Britton had pointed out that some cases of so called "gout at the stomach" (there was really no such disease) were examples of angina pectoris

Dr. Seymour Taylor said he had found that these cases grouped themselves under three headings: (1) Those where the symptoms were referable mainly to the cardio-vascular system; (2) a neurotic group; (3) cases of reflex origin.

Dr. Douglas Powell, in reply, said two opinions seemed to be current as to the nature of the pain—one that it was due to spasm or distention, and the other that it was of the nature of a neuralgia. To his own mind the theory of spasm or distention presented the most attractive features, and the more he thought over it the more difficult he found it to conceive of the pain as being of neuralgic origin. He admitted the difficulty of the objection that the heart sometimes preserved its equability of action during angina. He was unable to agree with Dr. Broadbent and others as to the rarity of mitral regurgitation in angina.

Professor Gairdner and Dr. James Ross, who were unable to be present at the debate, sent written communications. Professor Gairdner wrote to say that he still maintained the opinion expressed in the article he contributed some years ago to "Reynolds' System of Medicine," viz., that Nothnagel's angina pectoris vasomotorea was not a true clinical description of facts running parallel with Heberden's angina, and that the name was a most misleading one.

Dr. James Ross presented a theory to account for the distribution of the pains in angina and in other visceral diseases. This was to the effect that when a viscus was diseased there was local pain which might be regarded as of splanchnic origin (præcordial pain in the case of the heart). In addition, the irritation was conducted to the portion of the spinal cord from which the viscus derived its splanchnic nerve, and thence spread in the gray matter of the posterior horns, whence by the law of eccentric projection it was referred to the termination of the somatic nerves derived from the segment of the cord—the second and first dorsal in the case of the heart. The irritation might also (in the case of angina) be conducted in other directions, of which Dr. Ross gave examples.

London, March 21, 1891.

Dr. Broadbent is the "Lumleian" Lecturer for the present year at the College of Physicians, and has selected as his subject, "Structural Diseases of the Heart, Considered from the Point of View of Prognosis." Cardiac disease is a branch of medicine which has long been a favorite study with the lecturer, and one on which he is an acknowledged authority. In his Harveian Lectures for 1884 he discussed the subject of "Prognosis in Valvular Disease of the Heart," and the present lectures are virtually a continuation of his course before the Harveian Society. Of the structural alterations of the walls of the heart, observed the lecturer, some were extremely common, such as hypertrophy, dilatation, fatty degeneration; others were rare, such as cancer, syphilitic gumma, abscess, aneurism, localized fibrotic induration. He proposed to discuss only those which were comparatively frequent, and remarked that even as to these we found ourselves on much less secure ground than in dealing

with the valves. We were often left in some degree in the dark even by a post-mortem examination. In one patient, fatty degeneration had apparently proved fatal at so early a stage that the condition was scarcely perceptible to the naked eye; in another, the change had proceeded so far that it was scarcely conceivable how the heart had been able to impress any movement whatever on the blood. So with regard to dilatation, there was no fixed relation between the degree of enlargement of the cavities and thinning of the walls found after death and the interference with the circulation observed during life. While, however, attended with great difficulty, prognosis in structural disease of the heart was of much importance, for the cases were more numerous than those of valvular disease—far more numerous after middle age. Too commonly no attempt was made to recognize the existence and extent of degeneration and dilatation, and, no murmur being detected, the only diagnosis ventured upon was that of "weak heart."

Dr. Broadbent then proceeded to the consideration of cardiac hypertrophy. The prognosis of the condition, like the symptoms, was that of its cause, and the character and degree of hypertrophy were important, not so much in themselves or on account of danger likely to arise out of them, but as indicating the existence of some condition which had given rise to hypertrophy, and which was serious, possibly, in proportion to the hypertrophy which it had provoked. The causes of hypertrophy were then enumerated. If, said the lecturer, the condition were at any time produced by a mode of life entailing sustained muscular exertion, it was physiological and not pathological, and had no claims on our attention unless the initial change had been dilatation caused by violent and sustained effort, such as racing, the hypertrophy being secondary to this, but even then it was the dilatation and not the secondary process which had to be considered. In pathological hypertrophy the question of prognosis resolved itself into whether the compensation which it established was adequate and efficient, and how far it promised to be durable. The danger that the hypertrophy might go beyond what was required need not be considered. Compensation was efficient when there were no symptoms of embarrassment of the circulation, and when the heart responded to all ordinary calls upon it without undue shortness of breath or respiratory distress. The effects of exertion were an important criterion, due allowance being made for the greater liability to breathlessness in some individuals. The sounds of the heart usually gave notice when it was overtaxed by the resistance to the onward movement of the blood. The interval between the first and second sounds might be prolonged so that the sounds became equidistant; the period of repose and reconstitution of the muscular fibres was then shortened, and their nutrition must in time suffer. During systole the blood was squeezed out of the walls of the heart, and it was during the diastolic relaxation that it obtained free access to the cardiac fibres. Another evidence that the heart was yielding to the strain of overwork was reduplication of the first sound due to want of synchronism between the two ventricles. This was at first very slight, the two sounds being separated by the briefest possible interval, and being distinct one from the other only at one spot, just to the inner side of the apex; elsewhere there was only a slurring or prolongation of the first sound. Later, the sounds of the two ventricles were quite distinct, and the duplex first sound was recognizable over a considerable area, usually in the direction of the ensiform cartilage, but sometimes upward. Sometimes the dislocation of the ventricular first sound was so considerable that it was extremely difficult to identify the sounds of the heart at all and say which was first and which was second. The most striking and confusing examples were met with in aortic stenosis, but they occurred also in high tension. When the first sound was broken up in any very considerable degree the prognosis became serious. When cardiac hypertrophy had been brought about by high arterial tension, whether associated with renal disease, or gout, or other cause. There must also be taken into consideration the possibility that the powerful heart might rupture diseased vessels in the brain; if the arteries were conspicuously degenerated it was better that the heart should also undergo some degree of degeneration, and fortunately this usually took place.

Dilatation was then considered. The lecturer said it might be contrasted with hypertrophy rather than compared with it. It was not compensatory, but, for the most part, a confession of failure on the part of the heart muscle. There were, however, two exceptions to this statement; the dilatation attending aortic regurgitation was part of the compensatory arrangement and it was probable that the dilatation of the left ventricle met with in mitral regurgitation might have a similar effect. Violent or protracted exertion might induce temporary dilatation; it was better to speak of "distention" in these cases as special causes of dilatation of the heart (acting, no doubt, on pre-existing tendencies). Dr. Broadbent mentioned injudicious hydropathic treatment, the "Banting" method of reducing obesity, and inhalation of the fumes of Himrod's powder for the relief of asthma. Dilatation of the left ventricle was sometimes accompanied by a systolic apex murmur, obviously due to mitral incompetence induced by imperfect accomplishment of the constriction of the orifice; mitral valvular disease was attended with similar signs, but the presence of the left ventricle first sound in primary dilatation, and its absence in primary valve lesion, would sometimes be of service in the differential diagnosis of the two conditions. Discussing, then, the physical signs which were helpful in prognosis, the lecturer said that though there was nothing in dilatation to affect specially and directly the second sound, yet in proportion as the dilatation of the ventricles impaired the propulsive energy of the systole, so the second sound would be enfeebled, and the aortic second sound was usually weak as compared with the left ventricle first sound. Observation of the intervals between the sounds often supplied very important information. When, with dilatation of the left ventricle, there was resistance in the arterioles and capillaries (which was very commonly the case), the interval between the first and second sounds might be prolonged, and as this marked the duration of the systole it showed that the ventricle was trying to cope with the difficulty and complete its contraction. The systolic pause might be so prolonged as to equal the diastolic, and the sounds thus become equidistant, the first also having become short and sharp. On the other hand, the first and second sounds might be approximated, and as we could not suppose that a dilated and enfeebled ventricle completed its systole in a shorter time than normal, the only possible explanation was that it was quickly brought up short by the resistance in the arterial system, and expelled but a small portion of its contents. This shortening of the systolic pause was therefore a serious indication of failure of the ventricles, and, when carried to an extreme, so that the second sound followed the first immediately, and almost seemed to overtake it, it was significant of extreme danger. In two successive attacks of symptoms due to dilatation of the heart when the degree of dilatation appeared to be exactly the same, a difference in the length of the systolic pause was sometimes the chief, if not the only, point which made a difference in the prognosis. The first and second sounds were spaced in the first attack, which was survived; in the second and fatal attack they were approximated.

In Dr. Oliver's third "Gulstonian" Lecture he drew attention to the channels by which lead might be introduced into the system, viz., by the skin, by the lungs, or by the digestive organs. The experience of the lecturer was that the skin was a very suitable surface for the absorption of lead. In two of his patients, lead was found by Professor Bedson in the perspiration; if lead could be eliminated by the skin it must be capable of entering by

the same channel. There was no doubt as to the entrance of lead by the respiratory organs. When lead entered the body by the digestive organs it was found that the presence of proteid in gastric digestion reduced considerably the amount of lead dissolved. Lead passed into the system from the stomach chiefly as lead chloride, and neither as albuminate or peptonate, both of which were insoluble. Dr. Oliver thought that when lead passed into the system in drinking water contaminated with lead it was generally in the form of bicarbonate.

The relationship of lead to deranged metabolism was then dealt with, and particularly the association of lead and gout. Garrod's observations in regard to the deficient elimination of uric acid in plumbism had been confirmed by numerous observers. The lecturer laid stress upon the fact that gout in lead poisoning was not common in the north of England, though he admitted that gout itself was rarer there than in London. He questioned whether it was a true gout which occurred in lead poisoning and rather supported the view recently put forward by Sir William Roberts, viz., that the gouty diathesis and lead poisoning had a tendency in common to uratosis, or the precipitation of crystalline urates in the tissues or fluids of the body. The amount of urea passed in plumbism was usually deficient.

As to treatment, the lecturer had noticed that opiates, with castor oil, iodide of potassium, and sulphate of magnesia gave satisfactory results in colic; alum was not successful in his cases. Lithia had increased the amount of urine but had had no effect upon paralytic conditions. In the cases of acute lead encephalopathy, nothing gave such satisfactory results as the inhalation of nitrite of amyl and it frequently warded off convulsions. Pilocarpine had been successful where convulsions with complete suppression of urine had occurred.

In the Factories and Workshops bill now before Parliament it is proposed by the Government to abolish certifying factory surgeons.

A strenuous opposition is being organized by graduates to the latest scheme for the reconstitution of the University of London.

A PRACTICAL VIEW OF SEA-SICKNESS.

To the Editor of the Medical Record.

Sir: Being of a peace-loving profession—at least the upper half is—I do not write this in a spirit of war, nor do I quite agree with your editorial on the subject of sea-sickness, at page 15 of the Record for January 3, 1891. As a youngster I lived among and with sailor-men—men-o'-war's-men (my father being in the Navy)—and saw something of blue water, but more in-shore. I was always in or about ships and boats—usually having a sail boat at my disposal. At a rather early age for physical investigation I had a theory on the subject of sea-sickness, which, as time went on, I had no reason to find fault with, although I didn't know what to call it. Of late years I have laid all the blame on the vagus—primarily the eyes. I think the whole thing cerebral, with the stomach—through the vagus—aiding and abetting the misery. Here's my meaning, and I hope I will make myself thoroughly understood.

Take a "shore-going" person and send him aloft—the ship being in port and smooth water. I have known many who, on reaching the "top," had to hang on, or they'd fall overboard. I have tried to entice boys to the "cross-trees" and "jacks," but they said they were dizzy, and were afraid of falling. Later on, when these same boys were accustomed to the altitude, they followed me farther without a qualm—they grew accustomed to the altitude. Several of them complained of feeling sick at the stomach, and didn't get over it until they reached the deck again. One or two of them swayed so it frightened me, and without knowing any reason at that time for it, I shouted at them to shut their eyes, and on no account to open them until I said so. Meantime I lashed them to the shroud or a back-stay—anything firm—until they recovered from the dizziness, and then I "lay down" to the deck with them. This looks as though the unaccustomed height affected them, first through the eye, and the two were made sick by the "sympathetic" action of the vagus.

Similarly: People on board ship—shore-going people, mind you—have the unaccustomed motion of the spars, smoke-stacks, lanterns, etc., before their eyes. Sometimes let one of them stand still, holding onto a stanchion, and shut his eyes. Sometimes, but very rarely, this will stop sea-sickness—it has done it for me twice—"but," as R. Kipling says, "that's another story." Many who try this and fail of relief have still the imagination, and the ship's swaying, and their trying to keep their sea-legs in their mind's eye. Let these same people lie down and shut their eyes, and they're all right. I have, as a boy and youth, been on the water so much that I have tried with my sea sick friends many dodges. The above—supine position—twice I succeeded in heading it off; by making the subject lie on his face and shut eyes, have succeeded in almost every case. Furthermore, boy-like, I have succeeded in making people actually sea-sick on shore, by imitating the motion of the ship with my two hands, the thenar eminences together, and slowly swaying them, and opening and shutting them (like a shark's jaw). In a perfectly smooth sea, once when a boy, I drove two people below in this way, because the rest of us wanted the deck to ourselves. That the "muscular motion" isn't the invariable cause, this: I was at sea on board the Tallapoosa in 1876. One of my friends had a chum on board who had never even smelt salt-water. That boy hadn't any sea-legs in his kit, and charged around the deck like a regiment of cavalry over broken ground. He never lost his bright color, or spirits, and, heavens! what an appetite he had! He couldn't walk without assistance—he nearly fell overboard once. The Tallapoosa was an infernal old tub—she'd roll if you looked at her suddenly. This boy was a wonder. One day the whole of us were in the rigging; Captain (Lieutenant, actually) McRitchie sent some of the watch after us to tie us up, for "foot-money." They didn't catch me and another officer's son, but among others they tied this boy then. He staid "'cause he liked it," until mess-call, paid his little dollar, and "lay down" as pleased as he could be. Since I took my degree in 1882 I have advised people who were going over how to run the least chance of being sick—men and women. For two or three weeks before they sailed, I insisted upon a plain diet, and that the bowels should be thoroughly cleaned out and regulated. Several told me—or rather wrote me—afterward, that those directions enabled them to stay on deck the whole trip—something several of them who had been over before, had not been able to do. Fear has at times something to do with it. Even lying down with the eyes shut, the heavy rolling or pitching in a gale of wind, makes the stomach "feel as though it was coming out through the skin." As soon as the fear passes, by custom, that sensation goes. Later, they can go on deck, but the eyes must be accustomed to the unusual motion of things. When a boy, in 1873, coming north on this same old transport, the Tallapoosa, Senator Morrill was swung in a cot, steadied by guy-ropes, in the hurricane-deck house. I heard him tell my father that "if that confounded lamp wouldn't sway so," he'd be able to keep his interior department subject to some kind of discipline. He said the thing fascinated him so that he couldn't keep his eyes off it. It was "seized down," and the old gentleman was all right by next day. Why you should go to a German for a simple explanation of this common fact, I don't see. You know those animals will reject a simple explanation of anything, and turn loose on something deep and metaphysical—and, in my humble opinion, miss it altogether.

I have written a regular book—which I didn't start out to do, as this could be boiled down to one-third. I didn't write this for publication either, but if you want a subject for an editorial, you can use as much as you

choose of this, and abuse me in the bargain. I am too peaceful to fight. Oh! by the way, talking of "hardened sea-rovers," I know of an officer, and know another personally—he was navigator of a ship my father commanded twenty years ago—nearly, who never went to sea without being sea-sick, and this latter was a fine seaman, too. They were both retired on this account, as young men. The one I knew was nearly broken-hearted over it. He fought the weakness, but he turned out the weaker, and had to "give it up."

Very sincerely yours,

BERKELEY MACAULEY,
Captain Medical Department, U. S. A.

FORT LEWIS, COL., March 4, 1891.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 22, 1891, to March 28, 1891.

TILTON, HENRY R., Major and Surgeon. Granted leave of absence for one month, on surgeon's certificate of disability. S. O. 56, par. 5, Headquarters Division of the Atlantic, March 21, 1891.

BARTHOLF, JOHN H., Major and Surgeon, now on duty at Plattsburg Barracks, N. Y. By direction of the Acting Secretary of War, will proceed to Fort Wayne, Mich., and report in person to the commanding officer of that post for temporary duty. S. O. 64, par. 7, A. G. O., Washington, D. C., March 21, 1891.

GIBSON, ROBERT J., Captain and Assistant Surgeon. By direction of the Acting Secretary of War, the leave of absence granted in Special Orders No. 232, A. G. O., October 3, 1890, from this office, is extended one month. S. O. 65, par. 10, A. G. O., Washington, D. C., March 23, 1891.

JOHNSON, HENRY, Captain and Medical Storekeeper. By direction of the Acting Secretary of War, his retirement from active service this date, by operation of law, under the provisions of the Act of Congress approved June 30, 1882, is announced. S. O. 66, par. 5, Headquarters of the Army, A. G. O., Washington, D. C., March 24, 1891.

SWIFT, EUGENE L., First Lieutenant and Assistant Surgeon, now on duty at Fort Thomas, Ariz. By direction of the Acting Secretary of War, will report by letter to the commanding officer at Fort Grant, Ariz., for duty at that station, or at Fort Thomas, Ariz., as the commanding officer may direct. S. O. 66, par. 7, A. G. O., Washington, D. C., March 24, 1891.

GREENLEAF, CHARLES R., Lieutenant-Colonel and Assistant Medical Purveyor. By direction of the Acting Secretary of War, will proceed to New York City on public business, and thence to Boston, Mass., to represent the Army Medical Department at the American Association for Physical Education, and upon the completion of the duties contemplated will return to his station in this city. S. O. 67, par. 3, A. G. O., Washington, D. C., March 25, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 28, 1891.

AMES, HOWARD E., Passed Assistant Surgeon. Promoted to Surgeon, March 19, 1891.

WHITE, STEPHEN S., Passed Assistant Surgeon. Ordered to the Baltimore.

PICKERELL, GEORGE MCC., Assistant Surgeon. Promoted to Passed Assistant Surgeon, March, 25, 1891.

MARTIN, WILLIAM, Surgeon. Ordered to Naval Rendezvous, San Francisco, Cal.

WHITE, C. H., Medical Inspector. Appointed Fleet Surgeon, Pacific Station.

HARRIS, H. N. T., Assistant Surgeon. Ordered to the Receiving Ship St. Louis.

PICKERELL, GEORGE MCC., Passed Assistant Surgeon. Ordered to Naval Hospital, New York.

RUSH, C. W., Passed Assistant Surgeon. Ordered for duty with Inter-Continental Railway Commission.

OGDEN, F. N., Assistant Surgeon. Ordered for duty with the Inter-Continental Railway Commission.

NORTH, JAMES H., JR., Assistant Surgeon. Ordered to the Navy Yard, New York.

Medical Items.

Commitment of Insane.—The commonwealth of Illinois, and those also of Colorado and Idaho in quite the same measure, stands in a unique position among her sister States of the Republic with regard to the statute governing the commitment of persons alleged to be insane. Virtually, the person supposed to be insane is a criminal in the eyes of the law, and is legally dealt with as such. He is, upon complaint, brought before the open court at the county seat, tried before a jury of six, one of whom may be a medical man, and convicted and sentenced, or acquitted, according to the return of the jury. There is no discretionary power reposing with the judge as to the summoning of a medical commission. Again the law is unique, and highly absurd as well, in that, should the insane person be endowed with property, or some time after his incarceration become possessed of property by inheritance, it becomes necessary, in order that a conservator be duly appointed, for such insane person to be again publicly brought before a tribune, this time the probate judge, and the question of his sanity once more debated. And from this dual procedure verdicts have arisen directly opposed to each other. Then, again, the law makes but little, if any, provision for the release of a patient regaining a sane condition after commitment. The most serious evil, however, and the one it is desired to mitigate by legislative enactment so soon as it can be done, is to place a discretionary power in the hands of the judiciary, as between the open jury system and the calling of a qualified medical commission to examine, without publicity, into the mental condition of particular and given cases. At a joint meeting of the Chicago Medical Society and the Chicago Medico-Legal Society at the Grand Pacific Hotel, on February 16th, the entire session was devoted to a consideration and discussion of this question. Dr. Harold N. Moyer opened the subject by presenting a paper entitled, "Past and Present Laws Regarding the Legal Restraint and Detention

of the Insane for the Purpose of Care and Treatment." Following this, Dr. Sanger Brown read a paper on, "Proposed Changes in the Present Law Regarding the Legal Restraint and Detention of the Insane, for the Purpose of Care and Treatment, in the State of Illinois." And very much along the same line was a contribution from Dr. James G. Kiernan, headed, "Newspaper Reforms in Insane Asylums." Drs. D. R. Brower, Archibald Church, and others, took up the discussion, which plainly indicated the present feeling of the profession, and the absurdity—not to say absolute cruelty—which is imposed by the present statute. Dr. Sanger Brown, late of the Bloomingdale Retreat, presented a series of acts and provisions based upon the laws of New York, Massachusetts, and Wisconsin. Dr. D. R. Brower acknowledged the marked shortcomings of the present requirements; recognized fully the disadvantage of a public trial to the insane, and the lack of the protection it was believed to afford to the sane community. He had only lately found sane individuals under forced asylum restraint. Dr. Archibald Church reviewed thrillingly the cruelties of the present form, and cited a number of deaths resulting from the forcible conveyance, and appearance before the open county court, of insane persons. And to illustrate the danger of the rapid consideration of these cases in the open court of a large jurisdiction, as in the County of Cook, he mentioned the disposal of no less than fifteen cases of alleged insanity, in Chicago, between the hours of 10 and 11.30 A.M., being an average of six minutes for each case. It appears that at the last meeting of the Illinois State Medical Society this same question of the incarceration of the insane was discussed, which resulted in the appointment of a committee to look into and report upon new legislative amendatory possibilities; and this fact, coupled with the unity of conviction manifested at this joint meeting of these two city societies, caused the passage of resolutions, and the creation of a committee which is to act in conjunction with the one from the State body, and with the same end in view. Apropos to this subject, it may be mentioned that there is a very interesting bit of history connected with the original framing of this peculiar law covering the commitment of the insane in this State; and the same peculiar features have extended down since 1874—the period of its first enactment—in relation to whatever endeavors have been made to amend or alter. A woman—evidently a striking specimen of paranoia—with a most determined singleness of purpose, has stood, and still poses, as the one obstacle to the efforts of the profession. She wields an extensive influence at the State Capitol, and is so determined that the jury system shall abide inviolate, that only the most strenuous and pains-taking labors will bring about a repeal of the law as it is now written.

A Mohammedan Female Physician.—Dr. Razie Koutlairoff-Hanum, a young Mohammedan woman, who was born in the Crimea, recently passed a creditable examination as physician and surgeon at Odessa, and now enjoys the distinction of being the first woman of her creed to engage in the practice of medicine as understood by Western nations.

A Case of Fatal Rupture of Spleen.—Dr. Darwin records the following case: "A Sepoy, aged twenty-one, apparently healthy, fell in attempting to mount a bare-backed pony; he got up and walked about one hundred and fifty yards, when he 'felt queer,' and sat down, vomited twice, felt exhausted, and looked pale. He was quite collapsed when the doctor arrived; pulseless, and with sunken eyes. He referred to the left side of the abdomen as the seat of his pain, and died within two or three minutes. The body was opened half an hour after death, when a large quantity of blood was found in the peritoneal cavity. The spleen was carefully removed, and, on examination, was found to present two distinct points of rupture, the one below, the other on the upper and posterior surface at the upper curved portion. They were about an inch apart, the lower, which was the larger, being about an inch and a half long and half an inch deep. The spleen seemed to be about twice the size of a healthy one; the borders were rounded and the substance firm, but a small area around each rupture was soft and friable. The liver was somewhat enlarged; the other viscera were healthy." Dr. Darwin comments on the fact that the spleen was only moderately enlarged, while the injury was comparatively slight.—*Indian Medical Journal.*

Hæmolymph Glands.—It might be thought that after the careful search that has been made in all the tissues of the animal body it would be almost impossible to find a structure that has up to the present remained undescribed; yet Mr. W. F. Robertson, working under Dr. William Russell, in giving a careful histological description of his so-called hæmolymph glands, has opened up a new field for histological and pathological research. From the description given, the hæmolymph glands appear to be a kind of cross between the spleen and the lymphatic glands, as almost all the structures that Mr. Robertson describes may be found in one or other of these organs, although they have never yet been figured as he finds them arranged. Most observers who have noted the existence of the small prevertebral blood red points have assumed that they were simply lymphatic glands, the cortical spaces of which were distended with blood, and, although every butcher can point them out, it appears that no one has hitherto had sufficient curiosity to determine him to examine these structures microscopically. The large cells, with their colorless subdivided nuclei found in the sinuses, appear to be somewhat similar in character to the large red blood-corpuscle-forming cells that have been described in the spleen, and even free in the blood circulation, and it will be interesting to note whether it is possible to make out any relation between the cells in the blood and those in the hæmolymph glands. Although at first sight it might appear that Mr. Robertson's observations may lead to further complications in the study of the blood-forming and blood-destroying functions, we may hope that a careful study of the structures that he has so well described may allow of further light being thrown on these subjects. We are gradually drifting further and further away from the idea that special functions are necessarily bound up in special organs. That there is a special development in certain kinds of tissue in special organs, and consequently that certain functions are here carried on more actively, all will admit; but we are gradually coming to see that such functions as the glycogenic, hæmogenic, and the zymogenic are carried on in every part of the body, and that the various differences as regards these functions in the various tissues are those of degree rather than those of kind.—*The Lancet.*

An Eye to Business.—A certain doctor, who was noted for a keen eye to business, was driving along the street of a country town, when his horse took fright and ran away. He was thrown violently out of his trap and rendered senseless. Presently he recovered a little from his unconsciousness, and, noticing the crowd which had gathered about him, asked, "What's the matter, gentlemen? Anybody hurt? I am Dr. B——. Can I be of any service?"

Dr. Alvan Talcott, of Guilford, Conn., died recently at the age of eighty-seven. He graduated at Yale in 1824, and from the Yale Medical Department in 1831. He was one of the best of modern Greek scholars, and continued his studies to within a few weeks of his death. He was wealthy, and gave Yale College $25,000 to endow a Greek professorship. He was the author of a notable genealogical work, which gives the genealogy of the forty original settlers of Guilford. The work is in an imperial quarto, and contains twenty-five thousand individual names. He survived his wife and three children.

THE FREQUENT LOCALIZATION OF CIRCUMSCRIBED PLEURITIS BENEATH THE SCAPULÆ.

BY STANLEY S. CORNELL, M.D.,

ATHENS, ONTARIO, CANADA.

BEING the recipient of only the limited information that can be derived from a small library, I experience delicacy in producing my notes upon a number of cases representative of a peculiar manifestation of pleuritis which I regard as usual, but unnoticed, lest I repeat what some other physician has already placed before the profession. The remarks relative to the description of the following cases are such as individually illustrate a localization of circumscribed pleuritis that may be very frequently observed. Although but several short histories are given, they do not constitute the number that might occupy this paper. Some patients, whose histories fully sustain the characteristics of those whose notes I have taken, but in whom a lessened comparative volume and pitch of sound induced uncertainty of diagnosis, have not returned for re-examination; and the conclusions in these cases not having been confirmed, I prefer that they should be given no place in this report.

At various times since taking my notes of Case No. 1 patients have applied to me for the relief of wandering chest-pains, of "general debility," of "disordered stomach," and of cough, when a physical examination of the thorax would demonstrate the presence of pleuritic friction-murmurs beneath the scapulæ.

That simple myalgic or neuralgic pains should be accompanied by cough in one patient, disordered functions of the stomach in another, and general systemic weakness without evident anæmia in still another, presented causes and effects that were elucidated only by physical exploration of the chest in all its regions.

It may be said that I have recorded too few cases, and that conclusions as to the relative frequency of circumscribed pleuritis beneath the scapulæ can be arrived at only by a review of a vast number of such examples of the affection as we have under consideration. To this objection and affirmation I can reply by asserting that the number appears large, inasmuch as it has been collected from the few patients that usually visit the country practitioner's office for consultation; and that many other examples—though less pronounced in physical signs—have been before me.

The examination of the chest for the detection of these cases must be made with care, for there are many sources of error. The usual method of placing the patient in the position with the body slightly inclined forward and the finger-tips of each hand resting upon the skin overlying the upper margin of the opposite scapulæ is erroneous in the examination of the scapular regions. Frequently during the respiratory acts the palmar surfaces of the fingers, slipping over the dorsal skin, will produce a friction sound that closely resembles the pleuritic murmur. Therefore the appropriate position of the body for this examination is slight forward inclination of the thorax with the hands resting upon the thighs.

It will be difficult to locate the pleural sounds should the scapulæ be approximated too near the median line of the body in front. Another source of error may be found in the presence of a cluster of moist râles in the scapular region. I have known these to so closely simulate a pleuritic friction-sound as to render me certain in the diagnosis until successive acts of coughing by the patient had cleared the air-passages, when no evidence of pleuritic disease could be observed.

Error may also arise from the communicated sounds of articular movement in the adjacent shoulder-joint; this can be distinguished by its low pitch, greater extent, and rumbling character, better by its absence.

It is to be noted that the majority of these cases give a history of tuberculosis. I regret not having inquired into a history of rheumatism, either personal or hereditary.

CASE I. (October 28, 1890).—The patient whose history is about to be detailed has been under my observation for the past three months.

Mrs. H. J—— , aged forty-four; farmer's wife. The patient menstruates regularly every twenty-eighth day. Family history: The patient's mother died of "consumption," the age not being given. One sister died of "lung-consumption," the age not being given. One sister, aged forty, lives, and is the subject of pulmonary emphysema.

In June, 1889, the patient's left breast was removed for the eradication of a suspected (?) malignant growth. The growth possessed almost imperceptible characters, the breasts being symmetrical in outline, and palpation imparting the recognition of a slightly condensed state of the mammary tissue within a limited area at the upper and outer margin of the left mammary gland. The axillary glands were free from involvement, although the breast during a period of six months had been extremely painful. The following October, one year ago the present month, a fatty tumor, the size of a walnut, was removed from the outer extremity of the breast wound. During the time intervening between the two operations, neuralgic pains constantly emanated from the whole line of cicatrix left as the result of the healing of a septic wound.

The cicatricial tissue is adherent to the pectoralis major muscle in its entire course, and has induced a relative contraction of the adjoining skin. The left arm can be raised to the level of the left shoulder, but no higher, and can be made to come within four inches of the chest anteriorly, but no nearer. Within these limitations the movements are made with vigor. At this point of the examination inquiry, made to determine the existence of degeneration of the nerve fibres in the tissues included within the cicatrix and a consequent paralysis involving certain arm muscles, was met by negative results. Pressure by the finger along the scar yielded no tenderness, and, although pain passes over its whole course and thence to the left scapular region, there is no redness but that which would ordinarily exist in cicatricial tissue; no numbness, no tingling, nor loss of sensation in the parts immediate to, or remote from, the site of the cicatrix.

The pain, whose duration has been noticed, is variable in character. Sometimes it is felt as a sharp stitch, piercing the tissues with extreme severity; at others it is a steady ache.

Not convinced that the source of the pain should be referred to the cicatrix, I resorted to physical examination of the chest. Inspection: The only sign available under inspection was diminished expansion of the chest in the left infra-clavicular region. Percussion: Dulness

existed in the supra-scapular region, flatness in the scapular region above and below the spinous ridge. Auscultation: A harsh, grating, creaking, crumpling sound was heard in the scapular region, above and below the spinous ridge, with higher pitch; in the supra scapular region with lower pitch. The murmur is audible, with equal intensity in inspiration and expiration.

The respiratory murmur at the left apex was lessened in volume and pitch. During the period of my observation of this case all the evidences of persistence have been noted. There has been no cough, but the temperature has always registered 100° F. or 101° F.; while the pulse has been continually small, compressible, and rapid and the number of respirations abnormally increased. Besides the symptoms indicative of pleuritic disease there have existed those denoting functional derangement elsewhere. The tongue has constantly presented a white coating, the appetite been impaired, and the body-plumpness greatly disappeared.

Treatment.—This has been constitutional and local. To meet the general indications the mineral acids, with quinia, strychnia, and calumba, have been administered, and an attempt to combat the local condition has been made by the application of flying blisters of mustard to the scapular region, by the use of the ointment of the red iodide of mercury, of iodoform, and the tincture of iodine. Under these measures of treatment no improvement has been apparent up to the present writing. In addition to the remedies named the internal administration of the chloride of barium in solution was prescribed with no benefit. The patient having become anæmic, Bland's ferruginous pills were administered, although the temperature and condition of the tongue contra indicated the use of iron, with no benefit generally or locally. The prognosis probably points to final fibrosis and tuberculariza tion of the left lung.

Case II. (October 15, 1890).—M. B——, aged eighteen; farmer's daughter; single. Past diseases: Measles, scarlatina, and chicken-pox, from which good recoveries resulted. Family history: The point of importance in this portion of the patient's history centres upon the death of a maternal aunt from "consumption" of two years' duration.

All functions except those to be described are regularly carried on. The symptoms prompting consultation are those of a very mild subacute gastritis, pain in the stomach after the ingestion of food, pain upon pressure over the epigastrium, distention of the bowels and stomach with gases, coated tongue, headache, and dizziness. The temperature is normal, the pulse is small and feeble, but not unduly rapid, and the respirations are natural in length and number.

In addition to the foregoing symptoms pains, slight but troublesome, have been experienced in the left scapular region and in the interscapular region. The stethoscope reveals the presence of a friction murmur of variable pitch in the left scapular region below the central portion of the spinous ridge. During superficial respiration it is slight; in deep inspiration it becomes louder and is prolonged with but short interruption until the end of expiration.

Case III. (December 8, 1890).—S. J——, aged twenty-one; farmer. Past history: Measles, from which good recovery resulted. Family history: The family history includes long lives upon the maternal and paternal sides until it bears relation with the death of the father at the age of fifty four. I have it upon the authority of a very reputable physician that the parent died of cardiac failure, the result of depression induced by a sudden pleuritic effusion into the left sac.

Before considering the pleuritic affection to which this patient is subject, it may be well to announce that the physical signs of the precordial region yield proof of cardiac hypertrophy and dilatation. No history of pericarditis can be elicited, and valvular disease is not evident; we have only the story of heavy farm-work, and the probably resultant cardiac hypertrophy with secondary dilatation.

The symptom for which this patient seeks relief is pain situated one-half inch below the left nipple. This pain is constant in situation and intensity, and with it is associated shortness of breath. The "shortness of breath" is peculiar; neither inspiration nor expiration is diminished in length, nor is either hurried. Perhaps a suffocative sense overcomes the patient because of pressure of the enlarged heart upon the lung tissue. The physical signs are these: a friction murmur, audible during some, inaudible during other, inspirations and expirations, seated within a small area in the left scapular region below the spine, of high pitch but moderate intensity, with diminished lung expansion below the left clavicle.

Case IV. (December 26, 1890).—Mrs. W. K——, aged fifty two. Family history indefinite, unless the history of a prolonged illness occurring in a maternal aunt, in latest stages accompanied by œdema of the lower extremities, and ending in death, is *possibly* that of phthisis. Present condition: Pulmonary emphysema from right and left apices to a line drawn through both nipples transversely, and posteriorly on the right side beneath the scapular region; right lateral dorsal curvature of the spine; lowered apex beat with weakened first sound. Beneath the left scapula, above and below the spine, a low-pitched, grating murmur is heard during inspiration, varying in intensity during successive respiratory acts; flatness upon percussion exists, while, differentially, a tympanitic note is present in the right scapular region. The temperature is subnormal (97.5° F.), and there are present the physical signs of a general bronchitis.

Case V. (January 12, 1891).—Mrs. P. W——, aged forty-four; married; housewife. The patient is the mother of two children, whose births were not attended by complications immediate or remote. Family history: The patient's mother died of pulmonary tuberculosis at the age of fifty-one.

Physical examination: Circumscribed pleuritis in the left scapular region above and below the spinous ridge, emitting a harsh, creaking murmur, audible in inspiration, is detected by deep respirations; while emphysema at the left apex is shown by undue prominence of the thoracic wall in the infra-clavicular region, by a vesiculo-tympanitic percussion note, and by a high-pitched, prolonged, expiratory murmur. This murmur has been analyzed sufficiently to prove it non bronchial.

The patient is anæmic, and experiences, at times, dimness of vision and cardiac palpitation, while leucorrhœa, pain in the left iliac fossa, and weakness in the "small" of her back are her constant accompaniments. Through unthoughtfulness, I neglected the use of the thermometer, and further examination was denied me on the ground of delicacy.

Case VI. (November 25, 1890, 3.30 P M).—Mrs. M. McL——, aged twenty two; a medium-sized, well formed woman, with light skin and blue eyes; married; farmer's wife. Family history: Father lives, aged forty-seven, in good health. Mother lives, aged thirty-nine, in good health. One maternal aunt died of "consumption at the middle age."

The circumstances surrounding this patient have appeared to bear a causative relation to her present illness. Her father lay in bed a week before, attacked by severe lumbo-abdominal neuralgia, an affection exhibiting paroxysmal characters, and apparently contracted while recently ploughing a field. His temperature pursued such variations as at one morning examination to be 98.5° F.; at another 102° F.; at another 99° F.; at another 101° F., and I assumed that malarial infection had originated the febrile condition and neuralgic distress. Finally, three grains of quinine, given every second hour, for one week, removed all pain, and permanently reduced the temperature to 98 5° F.

The patient informs me that she feels much distressed by severe, continuous pain in her right shoulder, pos-

teriorly; that she is conscious of being feverish, and experiences thirst; that she has no desire for food, and her bowels are costive. Her tongue is coated with a white fur, evenly distributed over its dorsum. Her cheeks are flushed and her face slightly shrunken. Temperature, 101° F.; pulse, 100, small and weak.

From these symptoms I conjectured the presence of malarial fever with its chief expressions confined to the temperature, and the nerves in near relation to the muscles of the right scapula or underlying intercostal muscles. Physical examination of the chest negative.

Treatment.—The administration of five grains of sulphate of quinia four times a day was begun and persevered in for one week Two weeks later the pain had disappeared, the temperature was normal, and the appetite in a measure returned. Physical signs of the chest at the end of two weeks negative of disease.

January 20, 1891.—The patient has returned, feeling the scapular pain and coughing. Her temperature is normal, and pulse slow and full. The other symptoms are as before related.

Physical examination of the chest: A scratching sound pervades the scapular region of the right side above the spinous ridge, and is audible with greater length in inspiration; less audible during the expiratory act, and shorter.

Case VII. (February 6, 1891).—C. T——, aged forty-seven; farmer. Past history: The patient has been under constant treatment for twenty years, his physician having denominated his affections bronchitis and dyspepsia. Although these diseases are still present he experiences very little debility.

Family history: Father died at the age of seventy, of an unknown disease. Mother died at the age of forty years, from "consumption of the lungs." The only symptoms of which the patient gives an account are occasional cough, "weakness overspreading the whole body," and "pains in the chest." The pains are sharp, shooting from scapula to scapula, and passing down the arms; or resolve themselves into dull aching about the thorax, arms, and legs.

Physical examination of the chest: Pulmona y emphysema involves the infra-clavicular and mammary regions; beneath the right and left scapulæ scraping, tearing murmurs manifest themselves above and below the spinous ridges during inspiration and expiration.

SENSORY DERANGEMENTS FOLLOWING INTRA-CEREBRAL INJURIES[1]

By A. L. HALL, M.D.,

FAIR HAVEN, N. Y.

Gentlemen: It is only within a comparatively short period that the attention of the profession has been directed to the many and varied forms of sensory disturbances that are the resultants of trauma. Particularly true is this of the condition known as hemianæsthesia, which until lately was believed to belong exclusively to the symptomatology of hysteria. In the early part of the last decade so little was known of this symptom as a concomitant of injuries of the central nervous system, that such writers as Erichson, in his work on "Concussion of the Spine," does not mention it, and Page, in the last edition of his work on "Injuries to the Spinal Cord," merely alludes to a single case of injury, occurring in the practice of another physician, in which this symptom was present.

Owing to the vast amount of experimental and clinical research which has been conducted within the past few years, our present knowledge of hemianæsthesia, its production and correlation with the motor and special sensory disturbances which may coexist, has been to a considerable extent unfolded, and our knowledge of cerebral localization correspondingly increased.

[1] Read before the Cayuga County Medical Society at its regular annual meeting, held June 26, 1890, at Auburn, N. Y.

These investigations have determined that the sensory regions of the cerebrum are chiefly confined to the temporo-sphenoidal and occipital lobes, and that the posterior fibres of the crus cerebri are primarily involved in the transmission of sensory impressions from the peripheral portions of the body to the cortical areas of the sensory tract. The posterior third of the internal capsule, which lies between the extremities of the optic thalamus and the lenticular nucleus, is regarded as the sensory pathway, lesions of which induce hemianæsthesia of the opposite side of the body, with some interference of the other sensory functions, chief among which is crossed amblyopia with gustatory, olfactory, and auditory anæsthesia. In well-marked cases of hemianæsthesia the common sense of tactile impressions is diminished or abolished to the median line, including the lips and tongue. There is more or less abolition of the sense of pain and heat, which varies in different subjects. If the anterior two-thirds of the internal capsule is involved in the lesion, motor paralysis will be superadded to the existing anæsthesiæ.

In the posterior part of the internal capsule, in contiguity to the sensory pathway, lie the optic tracts; their proximity accounting for the frequent occurrence of crossed amblyopia in connection with one-sided anæsthesia. This condition of amblyopia is characterized by a concentric reduction of the field of vision and a moderately dilated state of the pupil. The frequency of crossed amblyopia, compared to that of hemianopsia, is much greater, the latter being a rarity, while the former is a quite common accompaniment of disturbed sensation. Hemianopsia most frequently results from the pressure of intra-cranial tumors, while amblyopia is generally due to direct lesions of the cerebrum and its basal ganglia. Pressure, destroying the conducting power of both the decussating and longitudinal fibres of the optic nerve, induces amaurosis, while in crossed amblyopia the decussating fibres lying in the region of the internal capsule are alone interfered with.

Generally speaking, all forms of anæsthesia are confined to that side of the body opposite to the cerebral lesion. In visual anæsthesia only one eye is commonly involved, and when the result of traumatism affecting the cerebral mass, it is almost invariably the sequence of optic neuritis. While vision in this variety of defect is much impaired, it is seldom completely abolished, and not infrequently it happens that, when sight is nearly extinct, some temporary improvement is seen to follow.

Auditory anæsthesia is usually confined to one ear, and may exist without the cognizance of the person affected. Exceptionally, this condition may be preceded by acoustic hyperæsthesia. This last named state is indicative of overtension of the auditory apparatus, or an irritation of the acoustic centre, while anæsthesia depends rather upon destructive lesions. Hence, anæsthesia is of a permanent character, while hyperæsthesia is of a more transitory nature.

Anosmia, or impairment of the sense of smell, results oftener as the sequence of intra-cranial growths than as a consequence of cerebral traumatism. It occurs in acute and chronic nasal catarrh from an alteration of the mucous membrane, and in paralysis of the fifth and seventh nerves. It is also of frequent occurrence in hysteria and in some kinds of insanity. It may affect one or both sides of the nasal cavity. When anosmia is complete, or nearly so, taste is impaired. Hyperæsthesia of the sense of smell is termed "hyperosmia," and is often present, as a temporary excitation, in many of the ordinary diseased states. Injury or neoplasms affecting the frontal lobes may induce this symptom.

Perversions of the sense of taste are known as gustatory hyperæsthesia, or hypergeusia, and gustatory anæsthesia, or ageusia. Hypergeusia is one of the many expressions of an abnormal state of the nervous system, and is the remote effect rather than the immediate result of disease or injury. When resulting from intra cranial

irritation, it is principally confined to one side of the tongue. Ageusia depends somewhat for its location upon the nervous distribution in the tongue, and consists in the partial or complete loss of the sense of taste in a part or the whole of this organ. It is observed after paralytic affections of the trigeminus and glosso-pharyngeal nerves, and in intra cerebral growths and injuries. This anæsthetic condition is usually associated with a similar state of the various sensory functions, the detection of one indicating the presence of the others. Especially true is this when hemianæsthesia exists.

The imperfect decussation of the pyramidal fibres of the sensory pathway has been inferred from the discovery of a similar condition in the fibres of the motor tract. This inference has to some extent been sustained by clinical observation, which, in some exceptionally rare cases, has revealed the existence of sensory disturbances upon the same side as the cerebral lesion. It would be a very narrow conclusion to assign to the sensory tracts a strict uniformity of location in the cerebral cortex, or to give to their converging fibres an exact definiteness as regards their limit and regularity of decussation. The most eminent students of cerebral localization never entertained such narrow views concerning the motor areas, but, on the contrary, believed that they existed as a complex system throughout the brain. If such views regarding the motor functions have been found tenable, why, in the light of our increased knowledge concerning the various sensory derangements, is not the conclusion justifiable, that the same law holds true in the distribution and arrangement of the sensory areas? While such a theory is not proven, it doubtless only awaits the progress of future developments to establish its truthfulness.

The study of the motor changes arising from brain traumatism has always kept far in advance of that of sensory disturbances. This, without doubt, is largely due to the more easy recognition of motor over sensory paralysis, as well as to the want of care and method in the conduct of the examination, and the failure to employ suitable diagnostic tests. With the use of the improved methods and aids at our command, the detection of the several forms of sensory anæsthesia is as easy and unfailing as the recognition of the different forms of motor paralysis. Furthermore, it is a well attested clinical fact, that an anæsthesia, or a hyperæsthesia, may be detected with as much certainty as a paresis. The coexistence of motor and sensory derangements is so frequent an occurrence that, too often, the failure to detect the former condition terminates the examination without any tests having been made for altered states of the special senses. Such examinations are a reproach to medical science, and are practised only by the uninformed or the indifferent.

Associated with cutaneous anæsthesia, there frequently exists hyperæsthesia of the most intense character. In such cases, the hyperæsthetic disturbances are usually present as a band, or zone, which may encircle the whole body or only affect a small portion. The cutaneous distribution of the brachial and sacral plexuses of nerves is the most frequent situation of exaggerated sensibility. The existence of localized hyperæsthesia upon the same side with hemianæsthesia of a central origin, is probably due to an associated excitation of the spinal centres for the hyperæsthetic nerves acting in conjunction with the cerebral disturbance. Hyperæsthesia accompanying opposite hemianæsthesia may be spinal or central in its origin. When the increased sensibility exists over a large area its central origin is probable. Hyperæsthesia of the spine is an almost invariable accompaniment of either form of altered sensation.

The physical changes which follow upon lesions of the sensory areas of the brain have received little attention from writers upon cerebral traumatism, consequently what is herein offered is based in part upon a few clinical observations, and largely upon the analogy between the psychical disturbances known to arise from lesions of the motor tracts, and those that are supposed to follow damage to the sensory regions. Patients in whom the cerebral lesions are moderately extensive, present an anxious and careworn expression. There is headache, hebetude of mind, loss of memory, inability for mental application, and periods of despondency. In some insomnia is present, while in others there is a strong tendency to somnolence. Again, there is emotional excitement, the usual phenomena of hysteria being manifested in all their intensity; or there may be the graver forms of psychical disturbances, such as epileptic seizures, mania, and melancholia. Among the most aggravating symptoms are hallucinations of hearing: ringing of bells, hissing, roaring, puffing, and other distressing sounds fill the head. The general impairment of the sense perceptions produce, in even the mildest cases, a form of mental obscuration amounting to an imbecility. This mind infirmity is seldom overcome. The bodily functions are imperfectly performed, and there is waste of tissue with feebleness and want of muscular power. In addition there are digestive derangements, which, with the existing impairment of the body and mind, makes life on the part of the patient in many cases a misery.

That the sensory derangements and the resulting psychical and physical effects, herein portrayed, have not been overdrawn, the history of the following cases will show:

Twenty six years ago, A. F——, aged twenty-one years, was injured by a branch from a falling tree striking him upon his left shoulder. He was unconscious for a short time only. For about a month following he was unable to do anything on account of the weakened and semi-paralyzed state of the entire left side of the body. There was some incontinence of the urine, which he states still annoys him to a slight degree. He gradually regained strength, and at the end of a few months was able to resume his duties. The weakness and numbness of the left side never completely disappeared. He had a very rapid and irregular heart action, which, associated with the weakness of the left side, greatly impaired his powers of endurance. Recently he was examined and the following conditions were noted: There is a general appearance of blunted intelligence. The heart beats 120 per minute, the rhythm is irregular, and its sounds and impulse are indistinct. There is slight hyperæsthesia of the lumbar spine, and hemianæsthesia of the left side of the body, which extends to the lips and tongue. Tests with the æsthesiometer show that the sensation is reduced for all parts of the affected side to one fourth that of normal sensibility. There is ageusia of the left side of the tongue, and auditory anæsthesia of the same side, hearing being $\frac{6}{4}$, while the right ear is unimpaired. The vision is affected, R. E., $\frac{1}{3}\frac{2}{0}$; L. E., $\frac{1}{8}\frac{2}{0}$. The tongue and left palate are sluggish, and there is slight paresis of the arm and leg of the affected side. The patellar reflex is diminished and there is a slight dragging of the left foot, the toe striking the floor in advance of the heel. In this case, the mode in which the injury was received would suggest a spinal lesion, but the symptoms show beyond question that the lesion is central; presumably involving the middle and posterior portions of the internal capsule, weakening the transmission of the motor impulse, and seriously interrupting the conduction of the sensory impressions.

In the following case, the history and notes are quite imperfect: A soldier in the late war was thrown from his horse to the ground, striking upon his head, rendering him unconscious for about an hour. Although able to be around his quarters, he remained off from duty for a month. At present he suffers from vertigo, pain in the back and head, loss of memory, numbness of the right side, and dyspepsia. Hemianæsthesia affecting the entire right side is present, and is associated with considerable muscular atrophy. Moderate hyperæsthesia of the cervical and lumbar regions of the spine exists. Vision is impaired equally in both eyes, being $\frac{1}{4}\frac{2}{0}$. The pupils are normal. There is no paresis, or evidence of former paralysis, present. Other forms of anæsthesia were not

discovered. Is pale and anæmic, the expression denoting mental obscuration.

In case third, the various sensory and psychical disturbances are well marked, motor derangements being absent. The history is as follows: Two years ago a strong, active laborer, aged fifty-four, was thrown from the top of a car, which was standing upon a trestle, to the floor below, a distance of thirty three feet, and buried underneath the car and its contents of coal. The region of the right hip and the inner aspect of the right knee were both severely bruised. There was a small superficial contusion of the right side of the head in the parietal region, uncomplicated by either depression or fracture of bone. He was severely shocked, and when seen, an hour after the accident, there was a rapid and feeble state of the pulse, with general coldness of the surface of the body. There was no loss of consciousness at the time of the accident. Reaction followed slowly, and at the end of the week he was able to get out of bed, although he was very weak and lame. Beyond slight mental confusion, the mind at this time was clear, and he was able when first seen to give a correct account of the accident in all of its detail. A few weeks afterward he called at my office. His face was pallid and careworn, and he complained of loss of strength and want of appetite, with inability to sleep. There was a rapid and weakened heart action, accompanied with gastric disturbances and various tracts of spinal hyperæsthesia, that of the lower half of the dorsal region being the most intense. Considerable emaciation had occurred in the interim, and it was plainly evident that he was suffering from the effects of the recent injury, which was rapidly developing the characteristic symptoms of remote lesions of the central nervous system consequent upon severe brain traumatism. Continuous observation of the case from that time until the present has fully sustained the truth of this inference, and in support thereof a brief summary will be given of the various symptoms presented. His weight, which at the time of the injury was one hundred and fifty four pounds, rapidly decreased, and within a few weeks thereafter he had lost nearly thirty pounds, which has never been regained. From the first there has been great loss of muscular power. A localized periarthritis developed at the seat of the knee injury, which subsequently resulted in a superficial necrosis of the inner condyle of the femur. Sacrodynia developed over the sacro-lumbar regions, being severest upon the right side in the region of the sacro-iliac synchondrosis. There is hyperæsthesia of the entire spinal column, it being exquisitely tender in the upper cervical, middle dorsal, and lumbar divisions, with spinal rigidity. He has aged rapidly, and the posture is stooping, the general appearances indicating a broken constitution. Memory is defective, and there is considerable confusion of the mind. Is irritable, morose, and easily excited. Becomes angry over trifles. The sleep is broken by distressing dreams. Has pain in the head, and roaring noises often disturb him. Complains of a constant numbness of the right side of the body. Examination discloses almost complete hemianæsthesia of the right half of the same, extending to the median line, and involving the lips and tongue. Is unable to determine the number or the situation of the points of the æsthesiometer when applied to any portion of the right half of the body, unless the distance apart exceeds from six to nine inches. At these distances he evinces a great deal of obtuseness and want of certainty as regards their application. The sense of pain is greatly diminished, puncture of the skin with pins being scarcely felt upon the affected side. The right half of the lips and tongue is markedly anæsthetic, while upon their opposite sides sensation is quite perfect. Taste upon the anæsthetic portion of the tongue is seriously impaired, so much so that common articles of food cannot be distinguished with any degree of certainty. Hallucinations of the sense of smell exist, while mild odor tests show a condition of partial anosmia, particularly of the right side. Hearing is impaired: R. E. $\frac{6}{6}$; L. E. $\frac{15}{40}$. Five months after the accident the left pupil commenced to enlarge. This condition persists, the pupillary borders having in the meanwhile become irregular. As the result of retinal degeneration, vision in the left eye is now reduced to $\frac{4}{200}$. There is concentric reduction of the visual field, the inner, middle, and outer circles representing respectively the color perceptions for dark green, red, and white when viewed at a distance of two feet. Vision in the right eye is normal, the field being unaffected. Monocular diplopia of the lower and outer field of the left eye was an accompaniment of the early ocular changes. Vesical irritability has persisted throughout, and is aggravated in consequence of the sacrodynia. The reflexes are weakened to a slight extent. There is, and has always been, a complete absence of paresis.

Briefly considered, this case presents all of the various forms of sensory anæsthesia, including the anomalous condition of amblyopia of the left eye. The present scope of our knowledge scarcely enables the definite determination of the full extent of the lesions which have induced this amblyopic condition. The probable conclusion would indicate that there is a want of the usual decussation of the deep optic fibres, thus affording an instance of a central injury with the visual disturbance occurring upon the same side as the lesion. Or, in other words, a unilateral lesion affecting the left side of the cerebrum, capable of inducing all the existing sensory phenomena.

From what has been said, it should not be inferred that sensory disturbances are always unilateral. On the contrary, many instances occur in which these symptoms are bilateral, or diffused over widely separated portions of the body. The consideration of these cases, together with many others of like character, has been purposely avoided, on the ground that neither the allotted time nor the scope of this paper will permit of their introduction.

In conclusion, the following deductions would appear to be sustained:

1. Sensory derangements occur alone, or in conjunction with motor disturbances.
2. The gravity of cerebral lesions, inducing solely sensory derangements, is quite as great as those which occasion impairment only of the motor functions.
3. The presence of one form of sensory anæsthesia is an indication of the existence of the others.
4. Those forms of sensory disturbances which most frequently coexist, are those of common sensation and vision.
5. Amblyopia is the most common visual disturbance, and while it is usually of the crossed type, it may occur upon the same side as the central lesion.
6. An anæsthesia has the same permanency as a paresis.
7. Hyperæsthesiæ most frequently depend upon local causes, while the anæsthesiæ are central in their origin.
8. Psychical disturbances which follow the sensory derangements are but slightly less severe than those which accompany the various forms of paresis.
9. Neurasthenia is generally a constant accompaniment of the traumatism which induces an association of sensory derangements.
10. The prognosis in the milder forms of sensory impairment is good. In those cases in which there is an association of the various forms of anæsthesia, the prognosis is grave. Improvement is not uncommon, while complete recovery is a rare event.

Cramps in the Legs.—Viburnum prunifolium is recommended for the relief of troublesome cramps in the calf of the leg occurring so frequently at night. This is an old remedy which has been used in domestic practice from time immemorial. The common name of viburnum opulus is "cramp bark," and its popular reputation for the cure of cramps and spasms used to be great and widespread.

SOME POINTS ON THE LOCAL THERAPEUTICS OF DISEASES OF THE NOSE AND THROAT.[1]

By WENDELL C. PHILLIPS, M.D.,

ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, THROAT DEPARTMENT, NEW YORK.

At the very commencement of this paper, to avoid being misunderstood, I desire to place myself on record as being decidedly in favor of conservative surgical procedures in a large proportion of the cases of chronic catarrh. The recent rapid strides in the surgical treatment of the various forms of naso-pharyngeal and laryngeal diseases have more than kept pace with similar advancement in other specialties. The nasal saw, snare, trephine, drill, forceps, scissors, and gouge, together with various other accessories, have taken their proper places in the domain of nasal surgery; and I venture to predict that in future days they will be looked upon as "the ancient land-marks which the fathers have set," and the labors of rhinologists will be in the direction of modifying and improving, rather than doing away with their use. It cannot be disputed that there is still room for greater perfection in our instruments, many of which are crude and unequal to the tasks imposed upon them; and as a result, many of our operations smack of the unsurgical. Notwithstanding these drawbacks, the results of these newer and more intelligent methods of treatment are satisfactory far in excess of the former modes, where very little or no surgery was resorted to. A perusal of the case books in any of our hospitals or clinics for nose and throat diseases, or of the private records of rhinologists, will reveal two quite radical changes, when compared with those of several years ago. First, the greater number of operations performed, and second, the shorter average attendance of the patients. The records of the throat department of the Manhattan Eye and Ear Hospital show only eighteen operations for an attendance of five hundred and forty patients in the report of 1881; fifty-seven operations for an attendance of seven hundred and forty-three patients in 1882, and six hundred and sixty-seven operations for an attendance of twenty-five hundred patients in the report of 1890. And it is interesting to note that while the number of operations has largely increased, the average length of time of attendance of the patients has largely decreased.

These facts lead to the logical conclusion that the patients are cured or relieved much quicker than formerly, and become strong arguments in favor of the more modern methods of treatment.

Again, in the earlier days men entered this specialty, many times only to abandon it after becoming discouraged and disheartened by the many failures. Now, the converse is true, and conscientious labor is being put forth to perfect every form of treatment.

All this is preliminary to the subject before us, viz.: A discussion of some of the medicines used locally in the diseases of the nose and throat and the best method for their application.

A word as to the use of the spray, an instrument that has been both extolled and condemned. By some it is used as much as ever, by others far less; and many have placed it among the antiquities, where it will not become clogged or broken any more. It has been called a germ-carrier, a thing unclean, and a source of many evils. But a good and useful instrument should never be discarded until something better has come to take its place. And nothing has yet appeared that will accomplish the work done by the spray, and no instrument now in use can be so well adapted for bringing medicines into contact with the diseased membranes.

Many of the recesses of the nasal chambers, pharyngeal vault, and larynx cannot be reached except by its use; and no conscientious rhinologist will attempt to treat his cases without the local use of medicinal agents either for the diseases themselves or for the proper healing of the wounds made in the various operations resorted to.

As to the spray tube being unclean, the same argument holds good in the use of all our instruments, nearly all of which enter farther into the cavities than the spray tube. It is no more difficult to sterilize a spray tube than any other instrument, and of course it should be done each time used.

A fact that cannot be disputed is that behind an unclean instrument is an unclean operator, and this kind of a criticism recoils from the instrument to the operator. The spray should be abandoned by no one, and especially by no physician in general practice. With a carefully selected series of medicinal agents he will be able by its use to treat successfully many cases.

There are so many medicines used locally in the various diseases of the nose and throat, that to even enumerate them would consume too much time. Suffice it to say that aqueous solutions, especially sprays, are used far less than formerly, and the rivers of Dobell's solution must hereafter flow into other than the nasal channels. This is not so because of any harm that has arisen from the use of aqueous solutions, but something better has come to take their places, and we part with them with the kindest feelings, for they have been faithful friends. To this rule there are exceptions, the most important of which is the solution of the peroxide of hydrogen, which, in addition to other qualities, is especially useful in the softening and removal of inspissated crusts, and for cleansing open sores and cut surfaces.

The failure to get good results from operations in the nose is due in most instances to neglected after-treatment. The conditions present in these cavities will not allow of an antiseptic dressing that may be left for three or four days and then removed with the expectation of finding the healing process completed, as may be done on other parts of the body, but healing in all cases must go on in the presence of septic surroundings. Thus the necessity for frequent and long-continued after-treatment in all operative cases, and the peroxide of hydrogen, used either by spray or cotton probe, stands at the head of the list of remedies that may be used to thoroughly cleanse the cut surfaces.

In his valuable paper on "Peroxide of Hydrogen and Ozone,"[1] read before the International Medical Congress at Berlin, Dr. Paul Gibier called special attention to the germicidal properties of this remedy. He quotes the experiments of Miguel, Bouchet, Nocart, and others, who sustain the theory that peroxide of hydrogen is one of the most powerful destroyers of pathogenic microbes, and believes the active element in this compound to be ozone. The remedy in his hands has been made to destroy various forms of bacilli and even the hydrophobic virus is rendered neutral by its presence. His paper closes with the following suggestions, which are worthy of quotation here:

"First. This chemical seems to have no injurious effect on animal cells.

"Second. It has a very energetic destructive action upon vegetable cells—microbes.

"Third. It has no toxic properties and is harmless when given by the mouth."

If this is true, then this valuable remedy, discovered by Thenard, in 1818, has never taken its proper place in the realm of therapeutics. Its disintegrating effect upon the diphtheritic membrane and its consequent tendency to lessen the activity of the inflammation underneath and around the patch cannot be denied. Experiments along this line have been carried on for some time by different observers, by merely applying it to the membrane. Dr. David Philips[2] recommends an application of the peroxide of hydrogen to the diphtheritic membrane, then scraping it all away with a curette, and following up the treat-

[1] Read before the New York County Medical Society, February 23, 1891.

[1] Medical News, October 25, 1890.

[2] New York Medical Journal, December 6, 1890.

ment by making frequent applications of the same remedy. In his cases the membrane has not returned after the first application.

In two cases of diphtheria I made use of Marchand's solution of peroxide of hydrogen, but first scraped the diphtheritic membrane and then rubbed it well into the surface where the membrane had been. After the first time it was merely applied with an applicator, and in both cases the inflammation subsided very rapidly and the membrane did not reappear except in isolated spots, and these were easily destroyed by another application. These were favorable cases from the outset, and probably would have recovered with ordinary treatment, but the method is well worth a trial.

Peroxide of hydrogen is useful also for arresting nasal hemorrhage immediately after an operation. The undiluted solution should be sprayed into the nose, where it will mix with the blood and form a firm clot that will arrest the hemorrhage by pressure, the same as ordinary tamponing with cotton.

The reason for the decline in the use of aqueous solutions for sprays is that we have been furnished with a better medium in the various products of petroleum that may now be obtained in a liquid form. They are palatable, non irritating, and capable of carrying many needed remedies in solution, all of which may be effectively used by an ordinary hand atomizer. They are soothing to mucous surfaces, may be used warm or cold, and they never clog the spray-tube. They may be made antiseptic to some degree by the addition of gum benzoin. When used as a spray, they are easily brought into contact with the membranes of the naso-pharyngeal tract. On account of their oily properties they remain on the surface of the membrane for some time, during which they not only protect the membrane from atmospheric influences, but give to it whatever remedy they may contain.

By various means liquid petroleum will take into solution, in varying proportions, nearly all the remedies now used locally in the upper air passages. Many of these enter directly into solution, while others must first form solutions with other drugs, chiefly animal oils, then they will retain their solubility with the petroleum solutions.

Some of the principal drugs referred to are menthol, eucalyptol, oil of eucalyptus, cocaine, terebene, thymol, carbolic acid, camphor, iodine, oil of gaultheria, tar, iodoform, and I have recently had a solution of aristol and liquid petroleum made which will be described later in this paper. All of these solutions may be used as sprays, but three or four of the more important ones will suffice for general use.

Dr. Charles H. Knight has been widely quoted as using menthol with liquid petroleum in the proportion of a drachm to the ounce. This proportion I consider far too strong for spraying purposes and is exceedingly painful and irritating to the membranes. Menthol should not be used in a proportion to exceed twenty grains to the ounce, and ordinarily ten grains to the ounce will suffice. Menthol is indicated in painful inflammatory affections that are acute, and in chronic catarrhal diseases that are painful in character.

Another spray made up of either the oil of eucalyptus or eucalyptol with liquid petroleum has taken the high rank it deserves among rhinologists. The eucalyptol is preferable to the oil of eucalyptus; it is less irritating, pleasanter to the taste, and can be used in smaller quantities. Besides, in about five per cent. of the cases, the oil of eucalyptus causes severe and prolonged attacks of sneezing. The eucalyptol should not be used stronger than half a drachm to the ounce, and the oil of eucalyptus not stronger than a drachm to the ounce, and they are indicated in cases accompanied by excessive secretion.

The menthol, eucalyptol, and liquid petroleum may, in the proportions above mentioned, be combined in one solution that will be found useful in many cases. Terebene may be used in the proportion of twenty grains to the ounce. Carbolic acid and iodine, of each one grain to the ounce, is sufficient for cases requiring these drugs, and thymol may be used ten to twenty grains to the ounce.

Recognizing the fact that aristol, the iodide of thymol, possesses many of the virtues of iodoform without its unpleasant odor, and finding that it has a marked influence on those forms of atrophic rhinitis manifesting the symptom known as ozæna, and also upon specific rhinitis, I suggested to W. H. Schieffelin & Co. that a solution of aristol in benzoinol might be made. They succeeded in doing so and a solution forty grains to the ounce, suitable for spraying, is now in the market. Van Horn & Ellison, druggists, make a solution of aristol and liquid petroleum as high as one hundred and eighty grains to the ounce, suitable for genito-urinary cases and surgical dressings, and application with cotton; but any solution above forty grains to the ounce is too thick for spray. I have found thirty grains to the ounce to be sufficient.

A short experience with this drug has given favorable results in several cases of atrophic rhinitis; but it is too early to say positively, whether the continued use of it will do more than correct the carrion-like odor of the breath and lessen the tendency to the formation of inspissated crusts. The odor of the breath has disappeared after a few days' treatment in every case, but the patients have been allowed to use the spray several times a day at their homes, and at each visit all the crusts have been removed.

Aristol may also be used alone or with other powders by insufflation. A solution recommended by Lowenstein [1] is made of aristol one drachm to flexible collodion one ounce, to be applied to mucous membranes, ulcers, or wounds. I used this form of solution of aristol successfully in one case of commencing specific ulceration of the septum and in four cases of slight ulceration of the septum due to "picking" with the finger. Aristol certainly deserves a fair trial, and the results so far obtained are favorable. Time will not permit a description of the results that may be obtained from many other drugs that are soluble in liquid petroleum.

Another drug has recently come into quite general use by rhinologists, and its popularity is due to the possession of qualities both styptic and antiseptic. The aluminium aceto-tartrate was first used in this country by Dr. O. B. Douglas, the president of your society, and the following is a description of the drug and its uses furnished by him, viz., "I first used the aluminium-aceto tartrate in February or March, 1890, in solution of about fifty per cent., applying it to the mucous surfaces in chronic hypertrophic rhinitis. This strength proved caustic in its action and I diluted it to twelve and a half per cent. I have found it most excellent as a disinfectant astringent after operations in the nose. It may be slightly painful when first applied, but this soon subsides. I know of no drug more serviceable for the purposes indicated. I think it was first used by Shaffer, of Bremen, and Lange, of Copenhagen, five years ago."

I have verified these recommendations of Dr. Douglas in many cases, but use it chiefly to arrest hemorrhage after operations. The method pursued is, to tampon the cavity of the side of the nose operated upon with absorbent cotton that has been dipped into a twelve per cent. solution of the aceto-tartrate of aluminium. The cotton may safely be left in the nose from two to four days, and the pledgets will be inodorous when removed, thus proving it to be possessed of important antiseptic qualities.

While there are numerous operations and various remedial agents for the cure of diseases of the nose and throat, he who would be successful in the treatment of his cases must take into careful consideration their physical characteristics, their constitutional and inherited tendencies and their hygienic surroundings. In the treatment of each individual case his attention must be directed to the hygienic, dietetic, and constitutional, as well as the operative and local requirements.

SOME PRACTICAL POINTS IN THE DIAGNOSIS OF TABES, AND THE SIGNIFICANCE OF CERTAIN SYMPTOMS.[1]

By WILLIAM M. LESZYNSKY, M.D.,

LECTURER ON MENTAL AND NERVOUS DISEASES AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; NEUROLOGIST TO THE MT. SINAI HOSPITAL AND DE MILT DISPENSARIES.

I HAVE no seductive theory to offer. No new doctrine to promulgate. No abstruse problem to solve. No original discovery to announce. Nor is it intended to supply a "long felt want" of medical literature.

The object of the writer is to present, from a clinical standpoint, a brief résumé of modern methods in the diagnosis of tabes.

This subject was selected after much thought, as being one of practical importance both to the general practitioner and the specialist. Not only the specialist for diseases of the nervous system, but also the ophthalmologist, the laryngologist, and the surgeon are frequently called upon to decide as to the underlying constitutional cause of certain unaccountable symptoms.

Tabes has generally been considered and described as an affection of the spinal cord. To-day it must be looked upon as a degenerative disease of the entire nervous system, although the most prominent and extensive lesion is found in the posterior columns of the cord. The pathological process may involve the cranial nerves as well as the peripheral nerves of the extremities. The brain, especially the cortex, is at times also affected.

The name "ataxie locomotrice" (locomotor ataxy) was given to this disease by Duchenne in 1858 and is still quite popular. It is objectionable because it is merely descriptive of a symptom, and that symptom may not appear until late in the course of the disease.

"Posterior spinal sclerosis" is also unsatisfactory, as it refers only to the most easily discoverable lesion.

"Tabes dorsalis" or "wasting of the back" was applied by Hippocrates to certain symptoms supposed to be due to venereal excesses, but was restricted to this disease by Romberg. The term "tabes," however, has lately obtained wider use, and is rapidly becoming universal.

The early diagnosis of a disease, which, so to speak, is chronic from the very beginning, as well as slow and insidious in its development, is of incalculable value, inasmuch as it saves the patient much misdirected and useless medication, and enables us to institute a rational plan of treatment. In many cases, where unrecognized tabes has existed for a long time, various pronounced symptoms may appear, and, although a part of the disease, may conceal its true character. "Correct observation is a matter of the greatest necessity; for on what we observe we have to make an interpretation and frame a line of action; consequently, if the observations are faulty, the interpretations we place upon them are valueless."

The classic picture of the well-advanced disease as described in the text-books is familiar to you all. A mere tyro in medical practice should be able to diagnose tabes at this stage where unmistakable symptoms are present.

Before emphasizing the prominent points in diagnosis, let us familiarize ourselves with the symptomatology. The symptoms which may appear in the early stage, or at any time during its course, which may lead to a recognition of the disease, may be grouped for convenience in the following order:

1. Sensory disturbances — the so-called fulgurating pains; cutaneous hyperæsthesia and anæsthesia; retarded conduction of sensation.
2. Abolition of the knee-jerk.
3. Visceral symptoms, known as "crises," affecting the gastro-intestinal tract, bladder, or rectum, and, occasionally, laryngeal crises.
4. Eye symptoms—such as myosis; inequality of the pupils; loss of pupillary light reflex; ocular paralyses; atrophy of the optic nerves.
5. Transient paralysis affecting the extremities.
6. Perverted sexual function.
7. Inco-ordination.
8. Affections of the bones or joints.

The peculiar pains may exist at varying intervals for years before any other symptom is complained of.

They are pathognomonic, and are characterized by the irregularity of their distribution, most frequently affecting the lower extremities, although they may occur in any portion of the body. They are almost always sharp and piercing, and are rapidly repeated at the same spot, which soon becomes excessively hyperæsthetic. These pains are only too often thought to be rheumatic or neuralgic.

At almost any stage of the disease recurring attacks of severe gastralgia may take place, accompanied by exhaustive vomiting which resists all treatment. Instead of these "gastric crises" there may be severe and unaccountable diarrhœa, which lasts for a long time, attended by violent colicky pain that may simulate an attack of renal colic.

Ignorance of the occurrence of these visceral symptoms is a common source of error in diagnosis.

Obstinate constipation is usual, and at times the patient complains of painful defecation or rectal tenesmus, or of a severe burning pain in the rectum as though a foreign body were present.

Incontinence or retention of urine is frequently an early symptom. Owing to paresis of the muscular coat of the bladder, considerable effort is required in micturition, hence, the bladder is not completely emptied, and the residual urine may undergo decomposition and thus set up a cystitis.

Paroxysms of true laryngeal spasm occasionally occur, resembling whooping-cough or laryngeal stridulus. These attacks may last from fifteen minutes to one or two hours, and have been known to prove fatal.

The pupils may be permanently contracted or unequal, and the reflex action to light may be absent. Frequently, diplopia is complained of, owing to a transient paresis of one of the ocular muscles (usually the external rectus). Or there is a permanent ocular paralysis. Atrophy of the optic nerves when it appears is generally an early symptom and may be mistaken for asthenopia.

This error would not occur if the ophthalmoscope were in general use.

Restriction of the temporal half of the visual field in conjunction with red-green blindness is highly suggestive of the tabetic origin of the optic atrophy.

A sudden motor paralysis of one or both extremities may take place and disappear in a few hours without leaving a trace.

Perverted sexual function may show itself in a suddenly developed impotence or a transient satyriasis. Exaggeration of the sexual function sometimes occurs in women, as the so-called "clitoris crises." These phenomena are by no means characteristic of tabes.

The peripheral nerves may become affected, but they possess the power of regeneration. This may account for many of the transient symptoms. This remarkable capacity for regeneration has been frequently shown after injuries and experimental nerve section. Such is, however, not the case with the central nervous system. Even after a year not a trace of incipient regeneration is discoverable, either in the posterior columns or in the posterior horns.

Then there is a peculiar affection of the joints, of a trophic nature, known as tabetic arthropathy. All of the joints may be affected. As a rule only one or two joints are involved. It may simulate arthritis deformans and lead to complete disorganization of the joint and the loss of the head of the bone. This condition may develop after a trifling injury, considerable swelling of the joint taking place, accompanied by extensive infiltration of the soft parts. The absolute painlessness of the entire proc-

[1] Read before the Mt. Sinai Hospital Alumni Association, January 27, 1891, and before the Newark Medical and Surgical Society, February 19, 1891.

ess, should at once direct the attention of the physician to the origin of the trouble. Spontaneous fractures of bones and the rupture of ligaments from very trifling causes are sometimes observed as the first indication of tabes. When inco-ordination or locomotor ataxia is noticeable, the nature of the disease is so evident that it only requires the demonstration of corroborative signs in order to reach a positive diagnosis.

It is not meant to imply that such an array of symptoms as have just been enumerated is found in every case. That would indeed be very hard lines for the sufferer. But it is well to be aware of the probable appearance of one or more of them during the course of the malady.

Tabes is the most common chronic disease of the nervous system, and its manifestations are numerous. Males are more frequently affected than females. The time of life during which it usually appears is between thirty and fifty years of age.

With these facts in mind, it is advisable, when we have to do with unaccountable symptoms, to make a more thorough investigation as to their origin, rather than depend upon empirical methods of treatment for their relief.

The earliest and most constant objective sign of tabes is the loss of the knee jerk. Berger and others have claimed that in about one per cent. of healthy people the knee-jerk is absent. The correctness of this assertion has been questioned. Its absence is invariably due to an obstruction in the reflex arc connected with the reflex centre situated in the lumbar region of the cord, in the segments corresponding to the second, third, and fourth lumbar nerves.

Thus it is lost in old age and in some cases of diabetes; in anterior polio-myelitis; or from a pathological process such as tabes or myelitis involving the posterior columns in the lumbar cord; or from interference with the integrity of the anterior crural nerve, as in peripheral neuritis; or as a result of neural or myopathic degeneration from local or constitutional causes. Owing to the absence of the knee-jerk, several of the conditions above mentioned are often mistaken for tabes, especially multiple neuritis. On the other hand, I have frequently had patients sent to me with the diagnosis of tabes, based upon a history of pains in the extremities, the presence of cutaneous anæsthesia, and the alleged absence of the knee-jerk, in whom I have been enabled to demonstrate that the knee-jerks were not only present but active. Occasionally much patience is required in satisfactorily determining whether the knee jerk is present or absent.

It is never safe to state that it is absent unless repeated and varied tests have been made and the clothing removed.

In many instances, the anticipation of the tap upon the patellar tendon occasions involuntary rigidity of the flexor group of muscles, thus bringing to bear sufficient opposing force to overcome the action of the quadriceps. During the examination the patient should close his eyes, and his attention should be diverted from the purpose of the examiner either by conversation or rapid interrogation. Or he may be directed to make some muscular effort with the hands, such as forcibly interlocking the fingers, or elevating the arms, etc. With this object in view, any other similar expedient may be resorted to that suggests itself to the examiner.

As has previously been mentioned, modern observers have shown that inco-ordination is not always present in tabes.

Yet, on the other hand, an erroneous diagnosis has often been made from the presence of this symptom. To tell a patient to put his feet together and stand with closed eyes is a simple matter. In case he sways from side to side or falls, we call this static ataxia, but although it frequently occurs in tabes, it is not of itself pathognomonic. A slight swaying is often noticed in healthy individuals.

Static inco-ordination is often present in hysteria or pronounced neurasthenia; during convalescence after prolonged illness; in transverse myelitis and in multiple neuritis from diphtheria, alcohol, lead, arsenic, etc.

In the condition known as the "Argyll-Robertson pupil" which is present in about four-fifths of all cases of tabes, there is absolute loss of the reflex action of the iris to light, while the pupillary contraction in convergence or accommodation is preserved.

This inaction of the pupil when exposed to light is not indicative of a lesion in the spinal cord, as was formerly supposed, before tabes rested upon a firm pathological basis; but is the result of interference with the reflex path in its course between the optic nerve, corpora quadrigemina and oculo-motorius. It is an infallible sign of central nerve degeneration, when the eyes are apparently otherwise normal.

The light reflex may be feeble or lost after fifty years of age, and is absent in some cases of cerebral syphilis and paretic dementia. The myosis found in tabes, however, is due to a degeneration of the sympathetic nerve fibres, which pass through the cilio-spinal centre in the cord.

In examining the pupils for reaction to light, considerable care is necessary. This is not so simple a procedure as it seems and is deserving of careful attention.[1]

The following method should be pursued: Place the patient in a position facing a window. Instruct him to gaze steadily upon some large object at least twenty feet distant, and to keep both eyes open. The eyes are then covered or shaded. In a few moments one eye is suddenly uncovered and exposed to light; when in the normal state the pupil (which always dilates in darkness or subdued light) immediately contracts. The other eye is then tested in the same manner.

The well-established principle that faulty methods in examination, like false premises in reasoning, result in erroneous conclusions, finds daily exemplification in the investigation just mentioned.

The pupils should not be examined before a gas flame, as the patient is apt to and generally does "fix" upon the flame, thereby causing contraction of the pupils in accommodation, which may mislead the examiner. A very common error to be guarded against, which is similar in its result, is the natural act of the patient in looking at the examiner as soon as the eye is uncovered.

The toxic form of multiple neuritis, most frequently from alcohol, is commonly mistaken for tabes. When the peripheral sensory nerves are markedly affected this condition has been termed pseudo-tabes. The presence of ataxia, both locomotor and static, with anæsthesia and the absence of the knee-jerk, all point to tabes. But as these symptoms are usually accompanied by tenderness on pressure over the affected nerve-trunks, diminished muscular power, or paralysis, and the electrical reaction of partial or complete nerve degeneration, we are enabled to exclude tabes. In some cases it is at first quite difficult to make the differential diagnosis. I have repeatedly seen transverse myelitis mistaken for tabes, owing to pains in the extremities, inability to stand with closed eyes, and cutaneous anæsthesia. Such an error is generally due to gross carelessness or neglect in the examination. The presence or exaggeration of the knee-jerk with possible ankle-clonus, and the loss of muscular power occasionally accompanied by atrophy should serve to make the diagnosis clear.

Paretic dementia and tabes are sometimes found associated, but where the mental symptoms predominate we must favor the diagnosis of the former.

I shall not dwell upon the differential diagnosis of tabes from the other diseases referred to, but wish to emphasize the fact that the loss of the knee-jerk alone or the mere absence of the pupillary light reflex is not sufficient for a diagnosis. As a rule, when these two impor-

[1] See "The Significance and Value of Pupillary Phenomena in Nervous Disease," by the writer, in the New York Medical Journal, March 31, 1888.

tant signs co-exist, it is sufficient evidence to warrant the diagnosis of tabes This combination is not always present, even when the disease is well advanced. But the knee-jerk is lost in every case. In the presence of any of the series of symptoms that have been described, particularly the fulgurating pains, the absence of the knee-jerk is corroborative of their tabetic nature.

It has been said that the larger part of our clinical work is based upon the statements of the patient. This is indeed true, in many instances, yet these statements are to be carefully sifted and the personal equation always considered. It is in the broad field of clinical neurology, which the physician has usually sought through predilection, and which is of absorbing interest owing to its special psychological features, that we are often compelled to accept the statements of the patient *cum grano salis*, and exclude the element of simulation As is well-known, many patients with constitutional nervous disease are often partly dominated by morbid self consciousness and undue introspection, which lead them into unintentionally exaggerated descriptions of their sensations. In tabes there are certain objective signs that cannot be simulated, to wit: the loss of the knee-jerk, the eye-symptoms and the joint affection. As nearly all of the other symptoms are more or less subjective, I have purposely refrained from their further discussion, preferring to confine most of my remarks to those symptoms which are only discoverable upon physical examination.

61 East Seventy-fifth Street.

Clinical Department.

TWO TYPICAL CASES OF LUPUS TREATED WITH GALVANO-PUNCTURE.

By A. WILBUR JACKSON, M.D.,

NEW YORK.

In mentioning these cases the writer is actuated by two motives. One is the wish to impel physicians generally to give an exceedingly valuable and much-abused remedy a fair and sufficiently studied trial; and the other, to point the way to those who may be already preparing to investigate. Since the excitement caused by the introduction of the first specimens of Koch's lymph has about died out, and the need of some effectual and safe remedy for such diseases as lupus, cancer, etc., is as great as ever, no evidence which goes to prove the existence of such a remedy as galvanism, properly employed, certainly is, should for a moment be withheld.

The cases to which I wish to draw attention are as follows:

Case I.—Mr. I. I. C——, of W— , a small village of Orange County, in this State, came to me for treatment about three months ago. He showed me an ulcer of the typical lupus nature, which had, he said, been actively destructive for only a year or so, but had given him trouble for three years past. He was given an ointment of resorcin, ichthyol, and vaseline, and every sixth day the entire circumference of the growth was subjected to puncture with fine platinum needles, the negative pole being the active one, and the séances lasting from five to ten minutes. The tissue involved at the commencement was about one half inch in diameter, and nearly round in shape, situated at the right side of the nose, just over the moustache.

At the commencement of the treatment the current used was cautiously and very gradually increased from five to twenty milliampères, but later, with the aid of a .04 per cent. solution of cocaine, the patient was enabled to endure a much stronger current and as high as fifty milliampères was employed.

At the end of about one month there was abundant evidence that the treatment was accomplishing the required work, and at the expiration of a little over two months the spot was entirely healed over and the patient pronounced cured. In order to satisfy himself still further, the patient applied to one of the large hospitals for an opinion as to the advisability of a course of the lymph, when he was assured by the physicians in charge of the department to which he had applied, that there was no use of lymph, or any other remedy, as he was beyond a peradventure cured! The gentleman thereupon returned to his home in the country, where he now is a well man, in so far as the lupus at least is concerned. This patient is an intelligent man, and will take pleasure in confirming the above history to any one interested in the study of the disease. It should also be mentioned, that red clover extract with potass. iod. were exhibited throughout the treatment, as the constitutional history of the case suggested such procedure.

Case II. is very similar to that just cited, in so far as the treatment is concerned, the patient being, however, of the opposite sex. The ulcer was a large and very deep one, and a source of great mortification from its disfiguring presence, not to mention the other grave aspects of the case.

In this, as in the case just cited, extract red clover with potass. iod. were exhibited throughout the course. The same current with the same ampèreage was employed, and with like results. The ulcer has healed, and what was an ugly sore which bade fair to result in the disfigurement and death of the patient, has disappeared, leaving a hardly noticeable cicatrix.

Of comse, I do not insist that success will invariably attend the treatment herein described, but give my experience for what it is worth, leaving it for others to test the matter for themselves if so inclined.

THE TREATMENT OF HERPES ZOSTER.

By GEORGE K. SMITH, M.D.,

NEW YORK.

Several years ago I met with a case of herpes zoster, in a blacksmith, thirty-four years of age. It was so good an illustration of the disease that I decided to take the patient with me to the clinic of the late Professor Samuel G. Armon, who was then lecturing at the Long Island College Hospital in Brooklyn. Professor Armon said that he was pleased to have the opportunity to exhibit the case to his class, for he had never seen a better illustration of the disease in his life. The eruption was over the course of the fifth intercostal nerve of the right side, and extended from the spine to the middle of the sternum. The vesicles were bright scarlet, intensely congested and painful.

Believing that the sufferings of the patient might be due to a local congestion where the fifth intercostal nerve is given off from the cord, I wet-cupped as near this point as I could; being careful not to let the cup rest on the inflamed skin. I took about two ounces of blood. As the blood was being drawn into the cup, I noticed that the bright scarlet color of the eruption was rapidly disappearing, "all along the line." The congestion was less, and when the cup was removed, the pain was gone. A little attention to the bowels was all that was done by way of medication, and in a few days the patient was able to go to his work. I have since had several cases which I have treated in the same way, with a like result.

GANGRENE OF THE SKIN IN AN INFANT.

By WALTER T. ROBERTS, M.D.,

LOUISVILLE, KY.

A case of gangrene of the skin which very recently came under my observation was so extraordinary in many respects that a description of it may be of interest to some of your readers.

It occurred in a healthy infant of nine months which was recovering from a slight attack of varicella, and

spreading with frightful rapidity terminated fatally in six days.

All the children of the family, eight in number, had the chicken-pox, the baby being among the last to develop it.

Before all the vesicles had matured there appeared on the left side of the head a circumscribed erythematous blush about three-fourths of an inch in diameter, followed rapidly by others varying in size from an eighth to one and a half inches. Within the twenty-four hours following, the epidermis would be slightly raised and peel off, leaving a not unhealthy surface beneath.

The anterior and lateral surfaces of the chest were invaded on the second day, and during the following night the left buttock became swollen, intensely red, and in the centre of the discoloration a greenish white patch appeared which under a poultice quickly sloughed out, leaving a deep ugly hole. About the same time there developed over the left pectoral region a number of irregular patches of erythema which coalesced, the skin becoming gangrenous in a few hours.

The majority of the blotches on the chest and neck assumed the greenish tinge and sloughed out, always leaving clean-cut deep cavities extending well down into the subcutaneous tissue. These holes varied in size from an eighth of an inch to an inch in diameter and occurred in great numbers. The large irregular patch over the left pectoral muscle was four inches long and two wide, involving about half of the axilla.

The child remained plump to the last, nursed almost ravenously, and died on the sixth day.

Whiskey and charcoal poultices alone were used in the management, but the rapidity of invasion and horrible course pursued by the eruption left small chance for recovery in an infant.

A CASE OF COLD ABSCESS OF THE EPIGLOTTIS, OF PROBABLY FOUR YEARS' DURATION.

By F. T. CHAMBERLAIN, M.D.,

WASHINGTON, D. C.

November 28th, 1890.—T. B——, male; aged twenty-eight. No specific history. Duration of uneasy sensation within throat, four years. There was slight difficulty of respiration at times, and a troublesome desire to swallow. Considerable dysphagia, which was the cause of patient applying for treatment. I failed to get any history of a foreign body or injury to pharyngeal or laryngeal cavities.

The patient was what might be termed a heavy drinker. Inspection showed a large buccal cavity, with a tumor extending behind and above the soft palate for about three-quarters of an inch, resembling exactly a small intestine inflated with air and of about the circumference of a keet egg. On swallowing the tumor would disappear, and reappear as soon as the act was accomplished. The surface of the tumor was covered with aborescent vessels originating from two main trunks running parallel with its long diameter.

There was only a slight inflammatory appearance present, which was probably caused by a drink of whiskey, which patient said he had taken a few minutes before examination.

The feel of the tumor indicated presence of fluid. There was considerable anæsthesia of the part, but I was unable to find the exact origin of the growth with the finger, owing to the length of the pharynx and the occlusion of the cavity by the body, and in consequence hesitated to make a diagnosis farther than of abscess. The use of the laryngeal mirror failed to help matters, owing to the obstructed view. On the following day, in the presence of Drs. Sinclair Bowen, J. V. Carraher, L. K. Batey, J. S. Saffold, and Mr. Sessford, I proceeded to aspirate the tumor with a small needle, after using a spray of a four per cent. solution of cocaine hydrochlorate, but this method proving slow and only getting a small quantity of thick yellow fluid, which later, under the microscope proved to be pus, I then made a small incision with a bistoury, and obtained a little over two ounces and a half of fluid, the sac contracting decidedly as the flow went on, necessitating the holding of the same with forceps to prevent its slipping from view.

After the entire evacuation of the sac, the appearance of the parts in the mirror was as if the patient had had a slight chronic laryngitis and epiglottitis. The epiglottis was slightly depressed in the centre, with a doughy look of the anterior surface. The vessels over the surface of the organ were enlarged and more numerous. Had one not acquainted with the former condition of the patient made an examination of the organ with the mirror at this time, he would never have suspected the previous existence of an abscess, and I was mystified myself, until after I had caught up the mucous membrane of the epiglottis, to account for the disappearance of the extra tissue. I then found that the entire mucous membrane of the organ, with the exception of a slight portion of the left side, was undermined, and in consequence of the elasticity of the tissue the membrane had contracted to almost its normal condition.

The appearance of the posterior surface of the pharynx, after removal of the tumor, showed clearly that the latter had existed for a long time, and tended to substantiate the history given by the patient. The sides of the pharynx about the pillars were highly hypertrophic, while the posterior surface extending up the back of the soft palate was worn away, and a depression was left so that there was almost given an outline of the bodies of the vertebra.

In the way of after-treatment, as there was no inflammatory condition, I prescribed simply rest of the organ, for a time, with a liquid diet, and the injunction to let me know at once in case of unfavorable symptoms. I did not hear from the patient until the following day, when I made an examination of the throat and found no inflammatory condition, although the sensation of something to be swallowed still existed, for which I gave sedative lozenges. Have seen patient a number of times since, and treated him for the pharyngeal trouble with partial success. Up to time of writing there has been no refilling of the sac and the epiglottis has returned to its normal size.

The above case is the only one of the kind that I can find reported, although I have searched the literature very carefully.

HYDROCHLORATE OF AMMONIUM BY INHALATION IN MEMBRANOUS CROUP.

By DWIGHT L. HUBBARD, M.D.,

NEW YORK.

It is not my purpose to propose a new remedy in the treatment of this disease, but to emphasize the importance of an old one. The beneficial results of the use of hydrochlorate of ammonium in eruptive fevers has been known for many years, but it seems to me few physicians fully appreciate its value and fail to obtain favorable results because of a lack of an experimental knowledge of its whole physiological effect upon the system. By "croup" I understand such cases as would properly and more scientifically be called "laryngismus stridulus" and laryngo-tracheal diphtheria. As many contend that we always have a false membrane of diphtheritic character in fatal cases of croup, those of us who have observed closely, learn at least to fear the formation of such membrane in "laryngismus stridulus" and often see the patients die with a fully developed "laryngo-tracheal diphtheria."

My idea in the use of hydrochlorate of ammonium is threefold: 1, As a heart stimulant, producing better oxidation of the blood by bringing it in more frequent con-

tact with the inspired air which is so deficient in quantity; 2, to relieve the spasm and the œdema of the glottis; and 3, to soften the false membranes. The ability of the remedy to do this is unquestioned.

Every practitioner knows that if he can successfully accomplish these three things he will feel that he is succeeding in benefiting his case.

The application of the drug by inhalation is what I would urge, having used it very successfully in my own practice. Place the patient in a small closed room, having a temperature of about 80° F., and generate sufficient heat under one drachm of hydrochlorate of ammonium to drive off the fumes copiously. Let this continue for fifteen minutes and repeat every hour. After each application ventilate the room as much as possible without reducing its temperature. Copious perspiration follows, the breathing becomes less stridulous, the mucus softer and more easily expectorated, and sleep generally comes to the exhausted sufferer. Of course I use other remedies in their proper places, but I depend mainly upon this treatment, and believe that only the best results come from it. Generally, the use of minute and oft-repeated doses of bichloride of mercury sufficient to act upon the glandular system, I believe helps materially. But I wish to particularize only on the use of the fumes of ammonium, hoping that the same satisfactory results obtained by me may follow its use by others.

344 West Thirty-third Street.

Progress of Medical Science.

An Early Symptom of Locomotor Ataxia.—The *Southern Medical Record*, quoting from German journals, states that Dr. Heinrich Weiss describes ataxia in a bookkeeper, whose first symptom was uncertainty in stepping backward. The importance of this initial symptom was pointed out by Althaus, in 1884, in reporting the case of a painter, who noticed it in himself as he stepped backward from the easel to view his work.

The Treatment of Earache.—Otalgias, according to Dr. Gompers, may be grouped as follows: The pain connected with otitis externa; the pain associated with otitis media; otalgia nervosa. In all cases it is violent. Otitis externa occurs either as a circumscribed furuncle, or as a diffuse inflammation of the auditory canal. In the first instance the pain subsides most rapidly if the furuncle is freely split open with a tenotome. If, however, the patient refuses to submit to this little operation, a solution of five parts of lead acetate and one part of alum in one hundred parts of water, applied on a small pledget of cotton to the furuncle, will lessen the pain materially. The bougies of Gruber may be substituted for the solution:

℞. Extr. opii aq..... 1 part.
Gelatin alb..... 50 parts.

These are introduced into the auditory canal, where they readily dissolve. The diffuse inflammatory condition is treated best with a five or ten per cent. solution of cocaine muriate, applied warm. Otitis media, which, as a rule, is associated with a myringitis, is characterized by the most violent pain. If the stage of suppuration has not yet been reached, the whole process may be anticipated by instillation of cocaine solution into the auditory canal, which is repeated every hour or two. Should this fail, carbo-glycerite of twenty per cent. strength must be employed, if we would obtain good results; if suppuration have already set in, and bulging of the membrana tympani becomes visible, paracentesis of the membrane will afford prompt relief. Antiseptic washes complete the treatment. In cases of chronic otitis this cleansing should be preceded by the application of fifteen or twenty drops of a five per cent. papain solution, which is permitted to remain for one hour, during which time the scales of hard, dry pus will soften and escape with the ear-wash. In contradistinction to otitis externa and media, otalgia nervosa is not dependent upon any aural inflammatory condition. It may be idiopathic, in which case there is often no cause apparent; or it may be sympathetic, the pain being reflected from some local condition of adjacent parts, *e.g.*, carious teeth, dental abscess, swelling or inflammation of the cervical glands, the throat, etc., and subsides when the affected parts return to health.—*Centralblatt für die gesammte Therapie.*

Treatment of High Temperature in Typhoid Fever and Phthisis with Small, Frequently Repeated, Doses of Antifebrin.—Dr. Favrat has treated a large number of cases with small, frequently repeated doses of antifebrin. He is strongly in favor of antipyretic treatment, as it greatly increases the comfort of the patient, and, by lessening metabolism, tends to husband the strength. The author points out at some length that most antipyretics are depressing, and that many of the newer ones are used rashly in practice, before we are thoroughly acquainted with their dangers, their doses, and the most effective ways of exhibiting them. When one reflects how long it has taken us to become even imperfectly versed in the possibilities to be attained with digitalis, opium, etc., we must conclude that new medicines are too lightly introduced, and in many cases too lightly cast aside. These considerations, and the fact that antifebrin, although a sure and active antipyretic, has certain drawbacks, such as the production of collapse, cyanosis, etc., have induced Professor Sahli and the author to try if they could not obtain the antipyretic action and at the same time avoid these drawbacks, by giving the medicine in small repeated doses, instead of in a single large dose, as is customary. The advantages of such a plan are obvious, as any unpleasant effects may be at once observed, and the medicine stopped before any serious harm has been done. Antifebrin acts rapidly, and is therefore specially suited for exhibition in small repeated doses, whereas a slowly acting antipyretic, such as quinine, either has no action in small doses, or causes a cumulative action after several doses have been given, thus losing the advantages to be derived from a divided dosage. In typhoid fever antifebrin was given in ½ to 1½ grain doses hourly in four cases. In no case was more than twenty grains given during the twenty-four hours. The action was satisfactory, and in all cases the temperature fell more markedly the higher it was. In seven cases in which similar doses were given every two hours, the reduction of temperature was scarcely sufficient. When the morning temperature was not over 101.5° F., however, a two hourly dose was found quite sufficient. Similar doses kept the temperature about normal in cases of phthisis. Neither in typhoid fever nor in phthisis did antifebrin exert any specific action on the course or duration of the disease. In all these cases antifebrin was well borne; a gentle antipyretic effect was maintained; in several cases sweating was present, but only in two was there the least sign of cyanosis or rigors. In no case was the patient ever much disturbed, and there were never any alarming symptoms. In conclusion, the author gives a warning against the use of large doses, three grains being reckoned as such. Although much larger amounts are often well borne, yet in certain cases fatal results have ensued. A number of such cases are cited.—*Deutsches Archiv für klinische Medizin.*

Insanity as a Symptom of Bright's Disease.—In the October number of the *Alienist and Neurologist* appears Dr. Alice Bennett's paper with the foregoing title—a paper read in June before the Medical Society of the State of Pennsylvania. Dr. Bennett emphasizes Hack Tuke's declaration that the psychological theory of insanity has prevented advance in the study of those forms of disease of which mental alienation is the most prominent, but by no means the sole, or even the most important, symptom. Blinded by psychology, a century of observation and the lives of hundreds of men have been lost.

Insanity is a symptom, or group of symptoms, that not always in its beginnings manifests disease of the organ of which it is the perverted action. Whatever the initial step leading to disordered brain action—exclusive of organic or developmental insanity—the remote effects are similar. If not checked, the process ends sooner or later in dementia—in the limited function of a more or less impaired brain tissue. The general practitioner is usually the one who has the opportunity of studying insanity in its inception, at the time when preventive measures may be attended with gratifying results. Sankey separates what he calls "ordinary insanity" from paresis, epilepsy, organic and developmental insanity. Speaking of the etiology of ordinary insanity, he says: "The disease consists in a morbid state of the blood, or of the processes concerned in nutrition." And he goes on to state that during the earlier period of the disease the symptoms are due to an alteration in the blood, in its quality and in its amount; there is some congestion with interstitial deposit of serum and of protein compounds; then atrophy of the brain substance and hypertrophy of the vessels. At first, symptoms are due to the circulation of impure blood; next to excessive supply; then they evidence the imperfect function of altered cerebral tissue. Following this trend of thought Dr. Alice Bennett makes some suggestions along a certain line that is the result of clinical experience. An analysis of sixty cases is given, together with interesting and instructive references to all the literature of the subject. The thirty-nine pages evince much care and thought, and furnish to the student a point of departure that may eventually lead to investigations of the greatest moment. The prophecy made earlier before the British Medical Association, "It is by chemical rather than biological investigation that the causes of disease will be discovered, and the power of removing them obtained," is constantly *en evidence*, and is every day making itself felt.

Mode of Entry of the Tubercular Poison into the Body.—Dr. Bollinger believes that the frequency of infection through the skin has been under-estimated. Several cases have been recorded of direct inoculation by wounds received from broken spittoons, by bites, operations, by earrings, etc. Eczema and impetigo increase the susceptibility of the skin. No case has as yet been attributed to vaccination, and it would appear that the tubercle bacilli are unable to live in the vaccine lymph. They also appear unable to pierce the pores of the skin as do some of the pyogenic organisms. The susceptibility of the mucous membranes is increased by inflammatory processes, such as otitis, rhinitis, conjunctivitis, and pharyngitis. The poison travels to the submaxillary glands and those of the neck, and generally causes local tuberculosis of the glands. The chief point of infection is of course the lungs. Local predisposition is best exhibited by apices which have been before diseased, but have undergone a healing process. The movement is deficient both in expiration and inspiration, and the liability to reinfection is increased by anæmia, irritants, constitutional influences, such as diabetes, disturbances of digestion, and unhealthy surroundings generally. The poison may pass through the lungs and attack the bronchial glands, under which circumstances the disease may be very insidious. The predisposition of the lungs again exhibits itself in metastasis; not every tubercular disease of these organs is due to inhalation of the bacilli or their spores. As regards primary tuberculosis of the testicles, joints, and bones, Bollinger considers that a latent hæmatogenic infection must be understood, which leaves as little trace of its point of entry as does a primary septic endocarditis or an osteomyelitis. Tubercular disease of the larynx depends upon an auto-infection through the sputum. The rarity of this disease in children is explained by the infrequency of pulmonary cavities in the rapid forms of phthisis. Primary tuberculosis of the intestine generally, combined with an affection of the mesenteric and retro-peritoneal glands, is usually occasioned by means of vitiated food and contaminated feeding utensils. Secondary tuberculosis of the intestine depends upon an auto-infection. The tubercular poison passes through to the intestine unaltered by the juices of the stomach and attacks the Peyer's patches and solitary follicles. Tuberculosis of the peritoneum, which is three or four times as common in men as in women, can arise directly from ulcers of the intestines, from tubercular abdominal glands, or, especially in women, from the urogenital tract; further, through contagion from the lungs and pleura, and finally in the course of miliary tuberculosis, or from caseous bronchial glands. Primary tuberculosis of the peritoneum is quite rare. As regards the infection from milk, this is, in Bollinger's opinion, undoubtedly due to the udder of the cow being affected with the disease. Infection through the milk of tuberculous women has not yet been proved.—*Münchener Medizinische Wochenschrift.*

The Organism of Cancer.—In the *Medical Press and Circular*, December 31, 1890, Dr. Jabez Hogg gives a passing view of his own searches for the characteristic organism of cancer, and of Dr. W. Russell's recent paper upon the subject of its discovery. Dr. Hogg calls attention to the fact that the spores of thallophytes and cellulares are always floating about in the air of town and country, and consequently they are often found in diseased structure exposed to the air for ever so short a time, and all decaying substances are naturally the seat of fungoid growths. Reflecting on the universality of the distribution of lowly organized vegetable bodies, and their known disposition to set up chemical decomposition in the pabulum on which they feed, places one at considerable disadvantage in any attempt to define the exact part the fungi play in any specialized form of disease.

"Astasia-Abasia" in Graves' Disease.—Dr. Eulenburg, of Berlin, discusses the state described by P. Blocq as "astasia-abasia." The author points out, first of all, that no consensus of opinion exists between Blocq and others who have written on the subject as to the true meaning of this morbid condition (*The Lancet*). Some consider it to be a mere symptom of a hysterical nature, while Blocq himself looks upon it as an independent morbid condition due to spinal lesion; Binswanger connects the symptoms with hypochondria, while Eulenburg observed a case of astasia-abasia during the progress of Graves' disease in an anæmic girl of eighteen, which shows that, apart from hysteria, a morbid condition may exist, not only comprising the symptoms represented by Blocq's description, but completely agreeing with their course and the effect produced on them by treatment. The girl had been treated for four months, and the goitre had not only considerably decreased, but the exophthalmos had almost entirely disappeared; palpitation and pulse became less frequent, and her whole nutrition had also considerably increased, when suddenly both her legs seemed to become paralyzed. She thought she had caught cold in a draughty passage. No other symptoms supervened. On examining the patient as to her sensibility and power of walking, the author diagnosed astasia-abasia, with a kind of self-suggestion as cause, as the patient had been seized once during the early part of her treatment with a sudden fear and consequent inability to pass over bridges. Psychical treatment was consequently indicated. The author informed her that a very painful and powerful remedy alone could do her good, but that this would cure her with certainty in a very few days. He applied faradism for about ten minutes below the knee and on the leg and foot most energetically, with rubefacient and of course painful effect. He then recommended some indifferent liniment and proposed to repeat the application of the faradic brush on the next day. Improvement was observed the same day, and one repetition of the treatment entirely cured the astasia-abasia.

MEDICAL RECORD:

PANDEMICS OF INFLUENZA.

MORBUS omnium maxime epidemicus were the words used by Huxham, in the last century, to characterize the disease which we have so recently seen circling the world from east to west, and which now, after an interval of rest, seems to be turning back in its course and traversing again the lands made miserable by its previous visitation. There is no disease, not even excepting cholera, which travels so rapidly and so surely, defying quarantine and despising measures of the strictest hygiene, and which embraces so universally in its bone-racking, muscle-tearing, sternutofactive grip the dwellers of the whole earth, the inhabitants of every region and every clime. Within the past four centuries there have been recorded nearly seventy wide-spread epidemics of the disease, thirty-six of which well deserve to be called pandemics, since they embraced the entire eastern or western hemisphere, many of them, indeed, like the present, involving the whole world.

Dr. Drozda, of Vienna, has recently published a translation of a work on influenza by Drs. Kusnzow and Herrmann, of Charkow,[1] which contains an interesting historical sketch of the different epidemics that have been recorded from the earliest times. The first mention that we find of any disease resembling influenza is that of Hippocrates and also of Livy concerning an epidemic occurring in the year 412 B. C. In 591 A. D. there was a wide-spread epidemic of a disease characterized by headache, loss of consciousness, debility, and an irresistible tendency to yawn, which some writers have regarded as influenza. It was at this time that the custom arose of wishing health or God's blessing on any one who was heard sneezing, since this was regarded as the first symptom of the prevailing disease. A number of supposed epidemics of the same disease occurred from time to time after this, but the first of which there are any satisfactory records is one that visited France and Italy in 1387. In 1410–11 there was an unmistakable epidemic of influenza, called by the chroniclers of the time "febris catarrhalis," which visited nearly the whole of Europe and attacked more than one hundred thousand people in Paris alone. Other epidemics of greater or less intensity were noted in 1427, 1438, 1482, 1505, and 1510. The latter was quite extensive, visiting all the countries of Europe.

The first pandemic known to have visited the western hemisphere was that of 1557. The disease appeared suddenly in the eastern part of Europe and spread rapidly toward the west, embracing all of Europe, then passing over the ocean and visiting the settled portions of this country.

This was followed by another epidemic in 1580, which was marked by an unusual mortality in certain places, more than nine thousand persons dying from the disease in Rome in a brief period. Numerous visitations are recorded in different places during the rest of the century, but the next marked pandemic occurred in 1657–58, arising seemingly in Switzerland and passing thence into Germany and England. Other epidemics were reported in 1675–76, 1679, 1688, 1691, 1693, and 1699.

During the eighteenth century a much greater number of epidemics was reported; but this may be because the records of these times are fuller than those of earlier periods.

The first was one of slight extent, occurring in 1702, followed in 1709 by one of much greater severity and wider area. The disease appeared again in a rather mild form in 1712, and this was succeeded in 1729–30 by one of the severest epidemics that have ever been noted. The affection appeared first in Sweden in the fall of 1729, and spread thence like a hurricane throughout all of Europe, reaching Iceland in March of the following year, and Mexico by way of Spain about the same time. Wherever the disease made its appearance almost all the inhabitants of the place were attacked; in Luzerne, for example, hardly any one escaped, in Geneva two thousand persons were suffering from it at one time, and in Moscow entire households were prostrated at once. The disease was not very fatal, but it had some illustrious victims, Pope Benedict XIII. being one of these. Another epidemic of very wide extent occurred in 1732–33, the entire world being visited by it, and for five or six years after this there were numerous outbreaks in one country or the other, climatic or other influences seeming to favor the continued elaboration of the poison. Huxham studied the disease carefully at this time, and he noted that its outbreak was preceded by an epidemic of the epizoötic among horses.

In 1742–43 appeared another epidemic of considerable extent, which was also preceded, in England, at least, by the epizoötic among horses and cattle. It was at this time that the name "la grippe" was first given to the disease in France. The visitation of 1757–58 was peculiar in that the disease appeared first in this country, spreading thence to the West Indies, and reaching Paris in June of the following year, though its prevalence in Poland had been noted several months before. The epidemic of 1761–62 also arose in North America, and took the same course, first to the West Indies and then to Europe.

The years 1767, 1772, 1775–76, 1780, and 1781–82 were marked by epidemics of influenza of varying intensity, the latter being one of considerable virulence. It began in China in the fall of 1781, arrived at St. Petersburg by way of Siberia in December of the same year,

[1] Influenza: eine geschichtliche und klinische Studie, von Dr. A. Ch. Kusnzow und Dr. F. L. Herrmann, Charkow. Nach den Russischen bearbeitet von Dr. Jos. V. Drozda. Wien: Verlag von Josef Safár, 1890.

and spread thence in a southwesterly direction throughout Europe. The disease was peculiar in that it would pass by some places entirely, while it raged with extraordinary severity in some neighboring localito. When it had once entered a town it would seize upon almost the entire population within a very brief period. Thus forty thousand persons were attacked in one day in St. Petersburg; in Vienna and Munich three-fourths of the population were attacked, in Rome two-thirds, and in Königsberg so many of the inhabitants were sick with the disease that all business was suspended. Three more epidemics were recorded during this century, namely in 1758, 1790, and 1798, the last two being confined to America.

The series of influenza epidemics of the present century begins with one of long duration, though of not very large extent. The disease was confined for the greater part to the northeastern portion of Europe, where it remained persistently for several years, spreading finally to China, Western Europe, and even to Brazil. The years 1807, 1811, and 1815–16 were marked by epidemics in America. The last one was of very mild character at first, the only deaths recorded being of the aged, but suddenly, and without apparent cause, it assumed a malignant form, the fatal termination coming often within eight hours after the onset of the disease. A notable epidemic was that of 1824–27, which spread over the entire continent of America, and ended in Asia and eastern Russia. One of the most extensive epidemics that have ever been seen, resembling in its wide spread prevalence, though we may hope not in its duration, the one through which we are now passing, was that which raged from 1829 to 1833. It was first heard of in China in the winter of 1829–30, and in September, 1830, made its appearance in Manilla, spreading through Borneo, Sumatra, Java, and all the regions in that part of the world. In January following it appeared in Russia, and during the following spring and summer attacked Northern and Western Europe, reaching North America in November, 1831. In January, 1832, it raged for a time in Spain, and then went back to America, attacking the West India Islands with especial severity. In the beginning of the year 1833 it appeared again in Russia, and worked itself out during the following summer in Southern and Middle Europe, where it was accompanied closely by the epizoötic. The number of sufferers from the disease was very large, reaching in some places one-third or one-quarter of the entire population. The mortality was also heavy, about one-seventh of the cases terminating fatally. In 1836–37 was another epidemic, which appeared first in Australia, then in Java, India, the Cape of Good Hope, and reached Europe within two or three months. The disease was particularly severe in England, where its mortality reached a high figure. Other epidemic years were 1850, 1852, 1855–58, 1860, 1863–64, 1866–67, 1870–71, and 1874–75. The latter, as will be remembered by most of our readers, was preceded in this country by a remarkably severe epidemic of the epizoötic, traffic in this city being at one time almost suspended by reason of the large number of horses stricken with the disease. The influenza that followed spread with great rapidity over both hemispheres. Since that time there have been several epidemics, but all of them, up to the present, have been of slight extent and of very mild character.

BEAUTY AS A MEANS OF HEALTH.

Before one of the New York Working Girls' Clubs, Dr. Louise Fiske Bryson recently gave an address upon this subject, reversing in more ways than one the usual order of copy-book aphorism. While acknowledging the impossibility of any protracted happiness without virtue, and the maintenance of beauty's fine edge without goodness, the doctor affirmed that systematic efforts to be beautiful will insure a fair degree of health, and that happiness is the best safeguard against vice. The difference in appearance between one woman and another, it was stated, is more than anything else an affair of style; that beauty of beauties so hard to define and so easy to recognize, which makes the girl of no-colored hair, features of indifferent turn, and lines none too perfect, infinitely more attractive than other maids of faultless curves and innumerable strong points not cemented by this magic quality. Style may be defined, for want of something better to express it, as an attractive manner of holding the body, a firm, graceful way of doing things, and of moving about. It is the visible sign of inherent power and reserve force. It is the outcome of long, deep breaths and the use of many muscles. The prayer of the New York child, "Lord, make us very stylish," when viewed aright, is recognized as an aspiration based upon sound scientific principles and worthy of universal commendation.

Proper breathing is the first art to cultivate in the pursuit of beauty. The lungs have their own muscular power, and this should be exercised. The chest must be enlarged by full, deep breathing, and not by muscular action from without. Inflate the lungs upward and outward, as if the inflation were about to lift the body off the ground Hold the shoulders on a line with the hips, and stand so that the lips, chin, chest, and toes come upon one line, the feet being turned out at an angle of sixty degrees. It is wrong to make the bony structure do most of the work in keeping the body upright. The muscles should hold it in position. In walking, keep face and chest well over the advanced foot, and cultivate a free, firm, easy gait, without hard or jarring movements. It is impossible to stand or breathe aright if the feet are pinched. When correct posture and breathing are interfered with the circulation is impeded, and deleterious substances in the blood tend to make the complexion bad. This is one of the many evils of tight shoes. To be well shod has a marked influence on style. The feet symbolize the body in their way as much as the hands. A clever shoemaker says that in a well-fitting shoe the human foot feels like a duck's foot in the mud. It is held firmly in place, but nowhere compressed. Nothing can exceed the vulgarity and hygienic wickedness of a shoe that is manifestly too tight. For misery-producing power, hygienically as well as spiritually speaking, perhaps tight boots are without a rival Next to the search for style pure and simple as a means of health, the care of the complexion and the cultivation of the right kind of expression are of great importance. The first is largely a matter of bathing and the general hygiene of the skin, while the second—a good expression—is best secured by the constant preference of higher thoughts over lower ones. This is the essence of intellectual living, and is fortunately within reach of us all.

Beauty that is lasting and really worth while, is more or less dependendent upon a good circulation; while a good circulation is made possible by correct pose, proper breathing, and the judicious care of the skin, something else is also necessary to insure the normal quality and activity of the blood. And this something consists in a combination of sunshine and exercise in the open air. Town-dwellers have too little of these blessings, partly from circumstances and partly from lack of wit. Exercise is the most important natural tonic of the body. Without it there can be no large, compact muscular frame. It is as essential to physical development as air is to life, and an imperative necessity in the maintenance of beauty. To keep the complexion and spirits good, to preserve grace, strength, and ability of motion, there is no gymnasium so valuable as the daily round of housework, no exercises more beneficent in their results than sweeping, dusting, making beds, washing dishes, and the polishing of brass and silver. One year of such muscular effort within doors, together with regular exercise in the open air, will do more for a woman's complexion than all the lotions and pomades that ever were invented. Perhaps the reason why housework does so much more for women than games, is the fact that exercise which is immediately productive cheers the spirit. It gives women the courage to go on with living, and makes things seem really worth while.

In a general way the great secrets of beauty, and therefore of health, may be summed up as follows: Moderation in eating and drinking; short hours of labor and study; regularity in exercise, relaxation, and rest; cleanliness; equanimity of temper, and equality of temperature. To be as good-looking as possible, and to be physically well, one must in general be happy. And to be happy it is necessary to carry out ideas of personal taste and preference, as many of them as can be put into definite form without infringing upon the rights of others. Happiness has a distinct æsthetic and hygienic value. In itself it will secure perfect poise and respiration. To be happy is a duty just as style is a duty, and both are in great measure an affair of intellect and management. The old order put the cart before the horse; it said: "Be virtuous and you will be happy," a rule with many exceptions. But the old order changeth. And the modern gospel postulates happiness and material prosperity as the basis of morality. Other times, other manners. The ardent pursuit of good looks sums up the best there is in hygiene, and becomes a legitimate and praiseworthy means of health. The world has yet room for two or three truths, of which not the least is the fact that the definite desire for personal beauty—which was in the beginning, is now, and ever shall be—constitutes in itself a perfectly proper and meritorious inspiration to effort, especially in a country where the shades of Puritanism linger as a sad inheritance, and where disinterred Buddhism claims too often the frail neurasthenic for its own.

ANTHROPOLOGY AMONG VILLAGE PEOPLE.

They do remarkable things in little towns. Our readers may not know that there is a new university, the "Clark University," in Worcester, Mass., with quite a number of mostly young workers and teachers who have the ambition of enriching science with new facts, and thereby adding to their own reputation and that of the institution. One of them is Dr. Franz Boas, well known in this country and in Europe for his geographical and anthropological writings. For the Canadian Government and our own he has been among the Indians of the far Northwest, after having sojourned among the Esquimaux of Baffin's land several years. This man had the courage lately of applying to the Board of Education in Worcester for permission to take measurements on school children, on the same principles and for the same reasons which guided our own Bowditch thirty years ago, Quetelet in Belgium, Virchow in Germany, and so many others. The Board of Education readily granted the permission, but one of the newspapers got convulsed with fright, warned the public, appealed to the children, proclaimed the Clark University people vivisectionists, who alternated between living children and dead cats; described poor Dr. Boas as a monster, a duellist, a fiend; published letters from villagers who threatened his life with shot-guns; called their Board of Education names for allowing "Fanny's nose" to be measured; scared President Hall into actual fear and pretended indifference about the whole matter, and proved that Worcester is no place for an institution of learning. Meanwhile a number of private schools have readily opened their doors to Dr. Boas; but the latest reports are that the morals of the Worcester paper are yet at boiling-point, and further subscriptions are welcome.

A BILL AFFECTING THE STATE BOARD OF EXAMINERS.

The *Buffalo Medical and Surgical Journal* calls attention to a bill which has been introduced into both branches of the State Legislature, and which, if passed, will entirely nullify the present law regarding the State Board of Medical Examiners. The bill confers upon the faculties of Cornell University, Columbia College, Union University, the University of the City of New York, the University of Syracuse, the University of Rochester, Niagara University, and Colgate University, the power to nominate an Examining Board to consist of fourteen members. This Board will have the power of granting licenses, and, in effect, it will restore in a measure to the faculties of the medical colleges that licensing power which the present law takes away.

The Medical Society of the County of Erie has condemned the bill, as have also the Medical Faculties of the University of Buffalo and the Niagara University.

ACTIVITY IN MEDICAL LEGISLATION.

The activity of the various Legislatures of the United States regarding medical and sanitary subjects is just now very extraordinary and interesting. It would hardly seem possible a few years ago that there could be so many things relating to the medical profession upon which one could legislate.

A passion for "regulating" everything has seized upon our law-makers. The Missouri Legislature, for example, wants to limit doctors' fees to fifty cents and a dollar, the California Legislature wants to regulate un-

dertakers and embalming, and the Illinois Legislature wants to regulate coroners' juries.

Other legislatures are proposing to regulate dentists, veterinarians, and tobacconists; while Arkansas wants to revoke the license of those doctors who do not behave themselves.

Missouri is proposing again to try the plan of regulating prostitution.

The attempts to secure laws providing for State Boards of Health are going on bravely. Bills have been introduced into the legislatures of Texas, Michigan, Nebraska, Pennsylvania, Rhode Island, Massachusetts, and, we believe, several other States. These bills have various degrees of excellence, but, on the whole, their tendency is good.

The same may be said of most of the attempts at legislation upon medical and sanitary matters. They show an increased interest in State medicine, a branch of human knowledge which has been too long neglected.

THE STATE BOARD OF MEDICAL EXAMINERS.

As we have not at any time consented or desired to be a candidate for the position of State Medical Examiner, our motives will not be misunderstood when we express some disappointment at the selection of examiners made by the State Board of Regents. We have nothing to say against the character or attainments of the gentlemen from Fredonia, Gloversville, Elmira, and other metropolitan centres. They are, doubtless, good men, but, with two or three exceptions, they are neither well-known nor representative.

Apart from this, however, we find that New York City, which contains more than two-thirds of the physicians of the State (2,265 out of 3,161), and which teaches and graduates more than four-fifths of the students, has no medical representative whatever.

Such apparent injustice is disappointing to the friends and promoters of medical reform, so many of whom reside in this city.

It is not at all surprising that a bill has been introduced setting aside the present law and providing for the appointment of medical examiners from the faculties of the various medical colleges of the State.

IMMIGRATION AND DISEASE.

Medical men, who see in this city such a mass of disease, filth, and utter unwholesomeness among the immigrants sloughed off upon us by Europe, will rejoice to learn that under the new laws there is some prospect of keeping out much of this injurious element.

Already, in conformance with the provisions of the new immigration law, which became operative April 1st, nineteen Italians, brought over on April 3d, were ordered to be returned to the ports whence they came. Four were debarred from landing on account of consumption, which is classed by the new law as a dangerous and contagious disease; eleven by reason of loathsome diseases, and the others are adjudged as likely to become public charges.

The new law requires a medical examination of each immigrant. The surgeons of the Marine Hospital are, we believe, engaged in the laborious and not very agreeable duty of making these examinations. If the Marine Hospital Service succeeds, however, in keeping out diseased and imbecile immigrants it will deserve well of the country.

News of the Week.

In the Missouri State Legislature a bill has passed the House requiring of medical students three years of study, three full courses of six months each, and a preliminary examination before matriculation is allowed.

Private Hospitals.—We commented some time ago upon the steady increase of these institutions in our cities. *The Weekly Medical Review* announces that three new private hospitals will soon be opened in St. Louis.

The New York State Medical Library.—The following circular letter, issued by the Legislative Committee of the Medical Society of the State of New York, explains itself: "Dear Doctor: At the last meeting of the New York State Medical Society a resolution, introduced by Dr. S. B. Ward, of Albany, was unanimously carried, urging the Legislature to take steps toward establishing a State Medical Library in connection with the General Library. In keeping with this resolution a bill has been introduced in the Senate by Mr. Sheard, and in the House by Dr. R. P. Bush (known as Assembly Bill, No. 926), making an appropriation of five thousand dollars annually and an additional appropriation of five thousand dollars for setting apart suitable quarters, building shelves, binding, etc., for the purpose of the above resolution. The consummation of this plan will be of vast benefit to the physicians of the State, as it is intended to keep on file all the important medical exchanges, to purchase all scientific books relating to medicine, and to send catalogues to the profession generally, in order that they may obtain, for a limited time, any volume on the shelves of the Library, on application, by paying the carrying charges. In order that this bill may become a law, a united effort on the part of the profession is essential. The session is about drawing to a close, and any work in behalf of this measure must be done at once. Will you kindly, therefore, personally solicit your Senator or Member of Assembly to advocate the passage of this bill, and if a personal interview is impossible, will you write them at once, urging favorable consideration of the measure? Very respectfully, D. B. St. John Roosa, Daniel Lewis, Maurice J. Lewi, *Committee on Legislation*, 71 Lancaster St., Albany, N. Y." We notice that an appropriation bill recently introduced provides $5,000, for connecting the Medical Library and the State Library. We trust it will not be stricken out.

Medical College Commencements.—Ensworth Medical College has graduated a class of twenty-three. The Northwestern Medical College of Toledo, O., has graduated a class of eighteen. The Medical Department of the University of Buffalo held its Annual Commencement on March 24th, and graduated a medical class of seventy, and a pharmacy class of thirteen.

Women and Coroners' Juries.—A bill has been introduced in the Illinois Legislature providing that women only shall sit as members of coroners' juries in inquests upon dead women.

Dr. Ransom Dexter, of Chicago, a surgeon of wide reputation, died at Chicago on April 2d.

The New York Medical Examiner is the title of a new monthly devoted to the interests of the practitioner in his relations as examiner. It is edited by Dr. G. W. Wells.

The Financial Value of Medical Examinations.—Physicians of this country are paid annually nearly a million and a half dollars for medical examinations for life insurance companies. Three companies pay over one-quarter of a million each.

The American View of It.—Our English contemporaries appear to be anxious that the medical profession shall be represented in the House of Lords. We trust, however, that no action will be taken to lower the present high standing of the British physician.—*Times and Register.*

The State Board of Health of Missouri has come out successful in a suit brought against it by an advertising quack. The Board refused the said quack a license on the ground of unprofessional and dishonorable conduct in the habitual publication of advertisements which in the opinion of the board tended, and were designed, to mislead and deceive the public, and impose upon sick and credulous persons by impossible claims of the treatment of diseases, and for the further reason that he was then engaged in the practise of medicine without a certificate and in defiance of the law. The court sustained the action of the Board.

The Virchow Celebration.—It is proposed to present a gold medal to Professor Rudolph Virchow on his seventieth birthday, which will take place on October 13th next. A fund is now being raised for the making of this medal, and the surplus, which, it is hoped, will be of good proportions, is to be handed over to Professor Virchow for the furtherance, subject to his decision, of scientific work.

Scarcity of Cod-Liver Oil.—It is likely there will be a cod-liver oil famine during the coming year. The number of fish taken in Norway this season has not been more than one-eighth of the average quantity, and the oil, which could be bought last year at $10 per barrel, now costs $40.

Fairfield County (Conn.) Medical Association.—The Ninety-ninth Annual Meeting of this Society will be held in Bridgeport, on Tuesday, April 14. Papers will be read on "Spinal Affections of Adolescence," "Inoculations with Koch's Tuberculin," and "Treatment of Pneumonia."

Dr. H. Willis, of Islip, L. I., died on April 1st, of pneumonia. He was born in England, and was fifty-eight years of age.

The House of Lords and the Medical Profession.—Colonel Fitzgerald has commented on the conspicuous absence from the Upper House of representatives of the medical profession. *The Lancet* says that the defect is an absurd one, and the minister who has the courage to remove it will deserve well of the public, and of the House of Lords.

Tubes for Tuberculin.—An order has been placed with a German firm of glass manufacturers for one million tubes of particular form and extra quality of glass, to be used for the general distribution of Koch's lymph.

Dr. James C. Healey, died in Albany on March 31st of pulmonary phthisis, aggravated by influenza. He was a graduate of the Albany Medical College, and was at one time the county physician.

A Treatment of Epistaxis.—Mr. Jonathan Hutchinson has made a note of a treatment of epistaxis which he avers has never failed of success in his hands, and he has had many very rebellious cases. It consists in plunging the patient's feet and hands into water as hot as can be borne.

Consumptive Immigrants not Allowed to Land.—Four Italian immigrants, who were found to be suffering from pulmonary tuberculosis, were recently returned by the Barge Office authorities to the vessel in which they arrived. The reason given for their return was that they were suffering from a "dangerous, contagious disease," which the new law ranks with pauperism and contract labor as barring admission to the country. Subjects of "loathsome disease" are also excluded, under the provisions of the same law, and therefore eleven cases of plica polonica were sent back.

Typhus Fever in Bellevue Hospital.—A male patient was admitted to Bellevue Hospital on Thursday, April 2d, supposed to be suffering from influenza. The symptoms, however, rapidly developed into high fever and delirium but it was impossible to make a diagnosis until just before death, when the temperature reached a characteristic high range, 106° F., and petechiæ appeared on the lower extremities. Active delirium continued until the end, on the Sunday following, when the temperature reached 108⅕° F. The autopsy was made by Drs. Herman Biggs and J. S. Ely. The brain was congested and there was slight œdema of the pia arachnoid. The lungs were densely congested throughout, as were also the intestines, with slight pigmentation of Peyer's patches. The liver showed considerable parenchymatous degeneration with general congestion, with the same pathological conditions in the kidneys. The heart was soft and flabby and its cavities were filled with dark, fluid blood. Considerable albumin was discovered in the urine during later days of illness, but urinary secretion was free. Petechial spots were scattered over the thighs, a few being found on the arms and trunk. Every precaution has been taken by the Health Department to prevent the spread of the disease. Typhus fever is exceedingly rare in this city, but twenty cases having been reported during the past five years, all of them originating elsewhere, and none of them propagating the malady.

Yellow Fever in Para.—The United States consul in Para reports that yellow fever has been very prevalent among recently arrived persons in that port during the month of January.

Dr. Charles Reyher, one of the most successful surgeons in St. Petersburg, died recently in Finland in consequence of an injury received while hunting. He was born in Riga in 1846, and was graduated in medicine from the University of Dorpat in 1872. He served in the Turco-Russian war, and settled in St. Petersburg in 1878, where his superior abilities soon won for him a large practice.

Dr. John P. Garrish died on April 3d at his residence in this city. He was born in New Brunswick, N. J., and was graduated from the Jefferson Medical College in 1836, and began the practice of medicine in the office of Dr. George McClelland of Philadelphia. He came to New York in 1840 and opened an office in White Street. He was one of the early members of the New York Academy of Medicine. His death was caused by cardiac and renal disease.

Dr. Avery Cook, the senior member of the Orange County Medical Society, died at his home at Otisville, N. Y., on March 30, aged eighty-three years and eleven months. He was born at Belchertown, Mass. Came to New York State in 1827, and began the study of medicine with the late Dr. Silas Loomis of Otisville. He completed his studies in 1834, when he was graduated from the Fairfield Medical College. He immediately entered upon a professional practice at Otisville, which he continued for fifty-six years. He married a daughter of Dr. Loomis, who died about a year ago, aged eighty years.

A Marine Hospital for Philadelphia.—Surgeon-General Hamilton, of the Marine Hospital Service, has been investigating the care given to sick sailors in Philadelphia, and advises that a hospital be constructed for their reception. Sick sailors were formerly attended to by the German Hospital for seventy-five cents a day, but the Jefferson Hospital secured the contract a year ago by agreeing to give medical care for one cent a head below the rate then paid.

A Room for Sick Nurses, called the "Mrs. Harry Ingersoll Endowed Room of the Nurses' Beneficial Association," has been established in the new Polyclinic Hospital in Philadelphia. The room has been endowed by the lady whose name it bears, and was opened for inspection and use on Thursday, April 2d, on the occasion of the formal opening of the new building of the Polyclinic.

Transactions of the Tenth International Congress.—It is announced that the first volume of the Transactions of the Tenth International Medical Congress is now ready for distribution among the members and associates. Personal application may be made at the office, Jerusalem Strasse 38, Berlin, S.W., or those who desire that their copy should be forwarded by post are requested to intimate this to A. Hirschwald, publisher, Berlin, transmitting the postage for the volume, which for the German kingdom and Austria-Hungary amounts to 30 pfennigs, and for foreign countries 90 pfennigs (about 10½*d.*) Due notice will be given of the publication of the sectional proceedings.

Paris Practitioners.—The number of medical men practising in Paris is stated to be 2,200, which, with a population estimated at 2,300,000, is equal to about 1–1,000.

Gynecological Differences.—*The Lancet* laments the difference of opinion among gynecological specialists: "One authority says it is quite easy to define an ovary—another not so. One says serious disease of the appendages is attended with menorrhagia, another with amenorrhœa. One sees danger in flushing the peritoneum, another does it almost daily; one says drainage should be abolished, another that it is most valuable. More than this, the teaching of experts as to errors in the organs of reproduction has undergone a wholesale change within a very few years, and the incidence of blame has been transferred largely from the uterus to its appendages. There is yet no guarantee that we shall not have other equally great changes announced."

The Sale of Professor Koch's Lymph.—The following official rescript has appeared: "Professor Dr. Koch has published in the *German Medical Gazette* of January 15th last, a description of the manner in which the lymph, discovered by him for the cure of tuberculosis, is prepared, and according to this description it appears that this remedy comes within the provisions of Section 1 of the Imperial ordinance of January 27th, of last year, and can therefore, with the exception of wholesale trade, only be sold by licensed chemists (apothecaries). Chemists can at present obtain the lymph, prepared under the personal supervision of the inventor, only through his authorized representative, Dr. Libbertz, 28, Lüneburgerstrasse, Berlin, N. W. It is supplied to them in special bottles of a capacity of 1 or 5 c.c. These bottles have glass stoppers covered with bladder and secured by a leaden seal, bearing the letter 'L.' On one side they bear the name 'Tuberculinum Kochii' in white letters on a black ground, on the other side a white label with the signature of Dr. Libbertz, and a note giving the date on which the lymph was prepared. Each bottle is accompanied by a printed paper containing instructions for its use. With regard to the preservation and sale of the remedy in chemists' shops, the following regulations must be observed: 1. The 'Tuberculinum Kochii' must be kept in the poison cupboard, and in the division reserved for alkaloids. 2. It can only be sold in the original bottles, and only upon the written order of an approved physician, and delivered to such physician himself or to a person authorized by him. 3. A record of the purchase and sale of the remedy must be kept in a special book, in which each bottle must be entered. The contents of the bottle, the date of preparation, of purchase and of sale, the name of the physician to whom it has been sold, or eventually, the removal of the unsold bottle from the shop, must all be noted. 4. If a bottle has not been sold within six months of the date of preparation marked upon it, it can no longer be sold or otherwise disposed of, but must be removed from the shop. Such bottles will be exchanged by Dr. Libbertz for others containing freshly prepared lymph free of charge. 5. The price of the 'Tuberculinum Kochii' is hereby fixed (exclusive of the cost of packing) at 6 marks for a bottle containing 1 c.c., and at 25 marks for one containing 5 c.c. I have the honor to request you to cause the above regulations to be communicated to the chemists in your district for their guidance, and also to take steps to insure their due observance.

"(Signed) DR. VON GOSSLER.

"BERLIN, March 1, 1891."

What Shall be Done for a Cold in the Head?—It may not be always possible to break up a cold. Sometimes during the congestive stage, anything which will allay irritation will suffice. The person who feels a cold coming on should instantly betake himself to bed, drink a cup of hot ginger-tea, and make use of a snuff like that which was proposed several years ago by Dr. Ferrier:

℞. Morph. sulph..... gr. j.
Bismuth subnit..... ʒ iij.
Pulv. acaciæ..... ʒ i.
M.

The insufflation of a little morphine at the commencement of a cold in the head is sometimes attended with very happy results. Quinine as an abortant in commencing cold is much in use; the dose should be somewhat large; Dr. T. J. Maclagan says ten grains. Its efficiency is, however, rather problematical. Doubtless, menthol is one of the best local applications in the early stages of a coryza. It may be used in the form of an ointment (menthol one part, vaseline thirty parts), or as a spray with liquid albolene. A formula which may do good service is the following: menthol, one part, liquid albolene, thirty parts. A special spray atomizer, such as is sold by all the instrument makers, is needed for the effective use of this combination. Menthol seems to limit congestion to the mucous membrane; it is often followed by a profuse flow of nasal mucus, with little sneezing. Breathing through the nose and mouth the steam of hot camphor water, and the internal use of carbonate of ammonia, are also recommended, and there is often utility in the production of active diaphoresis. Many of late years have claimed decided benefit from full doses of antipyrin, acetanilid, phenacetin, in the onset of colds; and, doubtless, these new remedies are more and more taking the place of the depressant diaphoretics. —*Boston Medical and Surgical Journal.*

University of the City of New York.—The annual commencement of the Medical Department of the University of the City of New York was held at the Metropolitan Opera House on Tuesday evening, March 24th, and at the same time the fiftieth anniversary of the school was celebrated. The principal address of the evening was made by the Rev. Dr. Henry Van Dyke. There was a graduating class of 203, and the valedictorian was Francis S. Kennedy.

Dr. Edward W. Crater, a physician widely known in Central New Jersey, died at his home at Oceanport, N. J., March 29th, aged thirty-two.

Regulating the Practice of Medicine in Massachusetts.—A bill bearing on this subject has been introduced into the House of Representatives. No medical board of examiners is created, nor medical society authorized to give permission to practise, the bill simply requiring that any one who intends to practise medicine shall appear before a city or town clerk, and describe, among other facts, his degree, or, if he have no degree, what preparation or experience he has had in medicine. The register is to be open to public inspection, and a list of persons so registered is to be published annually by the State Board of Health. A fine is to be imposed on all who practise medicine without registration.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 29, 1891, to April 4, 1891.

HOFF, J. VAN R., Captain and Assistant Surgeon. The leave of absence granted in Orders No. 61, c. s., Fort Riley, Kan., is extended twenty-three days. S. O. 36, par. 3. Department of the Missouri, March 27, 1891.

GIRARD, JOSEPH B., Major and Surgeon. By direction of the Acting Secretary of War, relieved from duty at Fort Lowell, Ariz., to take effect upon the withdrawal of the troops from that post, and to report in person to the commanding officer at Alcatraz Island, Cal., for duty at that station, reporting by letter to the Commanding General, Department of California. S. O. 70, par. 5, Headquarters of the Army, A. G. O., Washington, D. C., March 28, 1891.

BURTON, HENRY G., Captain and Assistant Surgeon, now at San Diego, Cal., on sick leave of absence, is relieved from further duty at Vancouver Barracks, Wash., and will report in person to the commanding officer at San Diego Barracks, Cal., for duty at that post, relieving Major David L. Huntington, Surgeon, and reporting by letter to the Commanding General, Department of Arizona. S. O. 71, par. 5, Headquarters of the Army, A. G. O., Washington, D. C., March 30, 1891.

HUNTINGTON, DAVID L., Major and Surgeon. On being relieved by Captain Henry G. Burton, Assistant Surgeon, from duty at San Diego Barracks, Cal., to report in person to the commanding officer at St. Francis Barracks, St. Augustine, Fla., for duty at that post reporting by letter to the Commanding General, Division of the Atlantic. S. O. 71, par. 5, Headquarters of the Army, A. G. O., Washington, D. C., March 30, 1891.

By direction of the President, the following-named officers are detailed for duty under the Inter-continental Railway Commission, appointed under a provision in the Act of Congress approved July 14, 1890, for the purpose of making "a preliminary survey for information in respect of a continental railway, recommended by the International American Conference," and they will report in person to the Commission in this city, accordingly: Captain EDGAR L. STEEVER, Third Cavalry; First Lieutenant STEPHEN M. FOOTE, Fourth Artillery; First Lieutenant LYMAN W. V. KENNON, Sixth Cavalry; First Lieutenant ANDREW S. ROWAN, Ninth Infantry; Second Lieutenant SAMUEL REBER, Fourth Cavalry; Second Lieutenant CHARLES A. WEDEKIN, Third Cavalry. Captain WILLIAM C. SHANNON, Assistant Surgeon, for duty as medical officer of the party to which he may be attached. S. O. 73, par. 9, Headquarters of the Army, A. G. O., Washington, D. C., April 1, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 4, 1891.

STEPHENSON, F. B., Surgeon. Ordered to the Marion.

BERRYHILL, T. B., Passed Assistant Surgeon. Ordered to the Marion.

WHITE, C. H., Medical Inspector. Ordered to the Baltimore.

CLARK, J. H., Medical Inspector. Ordered to the San Francisco.

HOEHLING, A. A., Medical Inspector. Detached from President of Naval Examining Board.

CRANDALL, RAND P., Assistant Surgeon. Promoted to Passed Assistant Surgeon, February 27, 1891.

BROWNELL, CARL DEWOLF, of Bristol, R. I. Commissioned an Assistant Surgeon, April 1, 1891.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, February 6, 1891.

GEORGE L. PEABODY, M.D., PRESIDENT, IN THE CHAIR.

Respiratory Movements and the Anatomy of the Thorax; A Report of Recent Studies.—DR. J. WEST ROOSEVELT read a paper with the above title.

The writer referred to the paper read by him before the Society and published in the New York MEDICAL RECORD of May 25, 1889, in which the statement was made that "it cannot be shown that any part of the lung moves, in proportion to its bulk, in respiration, less than any other." He dwelt upon the necessity in any study of respiratory movements, of remembering that not absolute but relative expansion and contraction are to be considered. If one lobe of a lung is in bulk one half as large as another then in order to cause the same degree of tension upon the elastic resistance of both that part of the thorax in contact with the smaller lobe must expand less than that which moves the larger. It is wrong to assume that if the upper ribs move less than the lower the apices for this reason are at any mechanical disadvantage as compared with the lower portions of the lungs. The question is not how much do the ribs move? but "how much do they affect the underlying lung, and how much is the latter expanded relatively to its bulk." He mentioned some of the conflicting statements made by various authors who attempted to explain the frequency of tubercular disease in the upper lobes, by theories based upon inhalation of tuberculous dust, defective nutrition, or the alleged insufficient expiratory movements of the parts which prevented them from expelling bronchial secretion and indeed, according to some writers, even permitted the lower lobes to force mucus, etc., into the upper, especially during cough ing.

The thoracic (female) type of respiration and the abdominal (male) type must not be forgotten by those who advance theories about pulmonary disease which are based upon any assumed difference between the relative or absolute motion in the upper or lower lobes.

The difficulty of obtaining trustworthy information in regard to the effect of dress upon respiratory movements, particularly among savage races, was mentioned. Naturally it is not important when considering the possible relation of chest movements to pulmonary disease, whether the difference between the male and female types in civilized countries results from dress or not. The difference certainly exists and may not be overlooked.

The writer thought that the smaller waists and larger hips of the female were the cause of the greater relative movement of the upper parts of the thorax.

The elastic force of the ribs as an aid to inspiration, pointed out by Powell, is too often overlooked. It serves to reduce the muscular work to a minimum.

If a lung be prepared so that it remains expansible after removal from the body, and if it be distended with air to its normal size, it will be seen that the apex is a rather irregular shaped hemisphere; that the lower portions may be regarded as irregular pyramids having four sides. The fact that two of these sides are convex and that one is concave does not practically make any difference when measuring the increase or diminution of the bulk from the whole pyramid. On watching the expansion and contraction of the lung, it is plain to the eye without measurements that the upper parts move very much less than the lower. It is also plain to the eye that any body of the shape of the upper lobe necessarily contains less lung substance than is contained in the lower. In spite of this its motion seems to be disproportionately small. When we remember, however, that the moving surface is practically a hemisphere, and that every fraction of an inch by which that surface is drawn away from the centre means an increase in bulk of one-half of the cube of that fraction, and that a sphere is a body in which the greatest possible bulk is contained by the smallest surface, it will been seen that the motion is not disproportionately small.

In regard to the lower lobe, its increase in bulk must be accompanied by a very much greater apparent surface motion (because of its pyramidal form). To make positive measurements of increase of bulk, it will be necessary to immerse the lung in a closed chamber with a hole through which a tube passes, connecting with the air outside and the bronchus within. The chamber being filled with liquid, the exact bulk of the collapsed lung can be ascertained. By pumping out a greater or lesser amount of the fluid, the degree of expansion can be absolutely determined. After this has been done for the entire lung, the bronchus communicating with one of its lobes may be plugged over while the lobe is completely collapsed, and then the bulk and the expanse of the unplugged lobe can be ascertained. Of course the actual minus pressure in each case must be noted. If an entire lung expands to a certain bulk under a minus pressure of M, then if the same minus pressure is exerted on either of its lobes, the same degree of expansion of the lobe will take place as took place when the whole lung was acted upon. In this way we can ascertain the bulk of the lung, the bulk of each lobe, and the total expansion of the whole organ, and equally accurately of every part of it.

What may be the effect of the air-currents in causing the deposit of dust in different parts of the lungs, is at present under investigation by the writer. Experiments are as yet too few to be of much value. This much, however, can be said, that so far I have found it absolutely impossible, under positive pressure, to force finely powdered ultramarine blue into the air-vessels, even after an hour's artificial respiration. The powder goes down to the small tubes, but not even to those branches of the bronchi which are nearest to the terminal branches. So far as seen, the powder behaves in exactly the same way one would expect it to do. It is deposited rather thickly along the trachea. If that tube be a long one, when the large bronchi are reached the deposit becomes less thick, but at the place of breaking up of a large bronchus into a number of smaller ones, a very heavy deposit takes place. This means, of course, that at such a place, the air-current becomes very much slower, inasmuch as the friction on the tube walls is greatly increased, and the current is diminished by this, and also by the greater transverse area of each pair of branching tubes, relative to the single tube from which they spring.

(A specimen was shown of a sheep's lung which had been, after removal from the body, made to inhale ultramarine under positive pressure for an hour, and fine pig ment was shown to be deposited in the manner stated.)

Savages as Mouth Breathers.—DR. SAMUEL SEXTON, in referring to the remarks made by Dr. Roosevelt upon the unreliability of certain statements handed down in the books as to the nose breathing of savages, said that he was reminded of certain investigations which he had once made on the truthfulness of the opinion that Indians were remarkably free from aural trouble. He found that, as a matter of fact, an unusual number of those whom he saw had some defect in the ears, and it was also his belief that the habit of savages to teach their children to breathe with the mouth closed had been overstated. Nor did he think mouth-breathing so dangerous as it was once said to be.

DR. DANA inquired whether the inhalation material employed by Dr. Roosevelt was a powder.

DR. ROOSEVELT replied that it was ultramarine blue ground to an extremely fine powder, and blown into the lung while practically dry or free from exudation. He thought, however, that the same laws would apply if the

substance were carried in vapor. He further stated that these experiments having been made under positive pressure, or by blowing into the lung, might give somewhat different results under negative pressure, *i.e.* inhalation or suction.

The Dumb-waiter for Comparison.—Dr. Andrew H. Smith said he had been interested in the remarks of Dr. Roosevelt upon the counter-balancing forces, retractility of the lung and elasticity of the chest wall. It might be compared unto a dumb-waiter, where the retractility of the lung would be represented by the waiter and the elasticity of the chest wall by the counterpoise. He believed that practically the retractility of the lung displayed a force somewhat greater than the elasticity of the chest wall. His reason for so believing was based on the fact that if a stopcock were put into the trachea of an animal which had been killed so that air could not escape and the thorax were then opened the lung would not fall back, but the walls of the thorax would spring out.

With regard to the place of deposit of the powder floating in the air carried into the lung, he thought that would be less likely to return which had entered branches at an angle than that which had entered branches whose axis corresponded to that of the trachea.

Lung Expansion Observed Through a Window.—Dr. W. G. Thompson said he had had occasion to study the expansion of the lung in the dog and other animals through a glass inserted into an opening left by excision of a rib, and as far as those observations were capable of doing so, they had confirmed the statements made by Dr. Roosevelt. They showed proportional expansion of the several parts of the lung. There was more friction between the parts in the dog than in man, due, he supposed, to the larger number of lobes and their overlapping one another during expansion.

Dr. Roosevelt said, with regard to the suggestion made by Dr. Smith, that he did not think the difference in the angle at which the bronchus was given off would have any influence on the relative amount of the powder deposited in different parts if the powder were very fine; it probably would if the powder were heavy.

Variability of Different Specimens of Parataloid.—Dr. Andrew H. Smith related a case bearing on the possible danger of changing from one specimen of the Koch lymph to another on account of variability in strength. He had been treating a patient for incipient phthisis for some time with a specimen of the fluid brought over by Dr. Bailey. He had increased the dose from half a milligramme up to three milligrammes and three quarters. At no time had it caused an elevation of the temperature of more than half a degree Farenheit. Ten inoculations having been given he then changed to another specimen of the fluid sent the Presbyterian Hospital from Koch's laboratory. Having last injected of the first specimen 3.75 milligr., he now injected of the new 4.5 milligr. The reaction was very alarming; the temperature jumped to 104.5 F., the pulse to 140, the chest became filled with mucous râles, there was some degree of cyanosis and great drowsiness. The reaction reached its height in about four hours after its commencement, or twelve hours after the inoculation. The temperature gradually fell to normal within four hours more, and the râles disappeared after twenty-four hours.

The case raised a doubt as to the uniformity of different specimens of the lymph, and considering that the lymph was a product of bacteria he could not understand how it was possible on different occasions always to make it of like strength. How could the number of bacteria or their activity be determined? The product not being chemical, a quantitative analysis was not possible. It would seem as difficult as to determine the peptonizing influence of the stomach of different animals.

The President asked whether the inference might not be drawn that the first specimen which had produced no influence was worthless.

Dr. Smith replied that the first specimen had produced the ordinary reaction in another case. He admitted that it had been diluted ten per cent. when it was given him.

Dr. Biggs said he had had a similar experience, but he believed the dilution of the first specimen had been made before he received it; when he received some undiluted lymph and diluted it himself, he obtained the characteristic reaction, which he had not obtained before.

Dr. Delafield remarked that the lymph would not keep diluted, and was not worth using when it came in that form.

Dr. Smith stated further that while the new lymph reacted somewhat more than the old on the other patient, there was not much difference. But aside from the value of this case, the question arose how was it possible to make different specimens of the lymph of the same efficiency?

The President said he understood the only test of uniformity in the fluid was its influence upon animals.

Dr. Smith doubted the reliability of even such a test, for different animals, like different persons, reacted under its influence differently.

Dr. Roosevelt remarked that if the variation were as great as forty or fifty per cent. it would not be greater than that of some of the tinctures made according to the directions contained in the Pharmacopœia.

Headache from a Cause hitherto Overlooked.—Dr. Samuel Sexton related a case of nocturnal headache due to a cause which he had not hitherto suspected. The patient, a man aged fifty, frequently awoke with pain in the head on the side on which he was lying. Having slight deafness and some subjective aural phenomena, he consulted Dr. Sexton. On examination, intra tympanic aëration on that side was found defective, the drum-head was sunken, and it occurred to him that the pain might be due to inward pressure on the stapes. As the man could not come to his office, he instructed him how to use Politzer's method on going to bed and when he awoke at night. Since he had commenced to thus practise inflation of the ear the headaches had disappeared. So far as he knew, this cause of headache had not before been recognized.

Primary Carcinoma of Lungs.—Dr. George L. Peabody presented a specimen of the above.

J. W. A——, thirty-three years of age, a native of the United States, a stevedore by occupation, entered the New York Hospital on January 10th of this year. He gave no morbid family history. He had never had syphilis, rheumatism, or malaria. He admitted that he indulged in spirituous liquors, but denied any excess.

About ten months previous to admission he had an attack of the "grippe," and this was followed by what was called pleurisy. Ever since then he has had at times pain in the left side and some cough. He was, however, able to be up and about until three weeks before he entered the hospital, when he thinks he caught cold. Since then the cough has been much worse, and has been accompanied by a good deal of mucous expectoration and pain in the left chest. At times the cough has been very violent, and has been followed by vomiting. He has noticed no blood in his expectoration since the attack of grippe. He has occasionally had night-sweats, and has lost much flesh and strength. His appetite is fair; his bowels are constipated. His chief complaints are cough and vomiting. On admission at 4 P.M. his temperature was 98° F., respiration 36, pulse 116.

Physical examination gave the following result: All over left chest, both behind and in front, percussion note is very dull, but nowhere absolutely flat. At the left apex in front, breathing and voice are somewhat exaggerated. Below apex, behind, in axilla, and in front, voice and breathing are very much diminished in intensity, but are everywhere distinctly audible. On right side, at apex, in front, percussion note seems somewhat hyperresonant, expiration is prolonged and high pitched, and voice is exaggerated. No râles are heard on either side.

Heart's area of dulness is normal; a blowing systolic murmur is heard at apex, which is transmitted toward axilla. Heart's action is regular, of fair force, and slightly accelerated. Organs of abdomen, normal so far as physical examination can detect. Tongue is broad, pale, and slightly coated. Radial arteries are somewhat rigid. Patient is pale, somewhat emaciated, but in fair general condition. There is no œdema. Urine is normal, except that its specific gravity is rather high (1027), and that it contains mucus, oxalate of lime crystals, and some pus-cells. He lived only eleven days after coming under observation. His treatment was supporting and symptomatic, including chiefly tonics and food and remedies addressed to his cough. On two occasions his sputa were examined for tubercle bacilli, with negative result. During these eleven days he was greatly troubled by cough, with muco-purulent expectoration, which was abundant and tenacious. Cough interfered greatly with his sleeping, and finally necessitated the use of morphine. He failed steadily, with no change in his physical signs, and died exhausted on January 21st at 9.35 P.M. Once his temperature reached 101° F., but it was rarely as high as 100° F., and normal much of the time.

The autopsy was made eighteen hours after death. The body was emaciated and anæmic. Lungs: On the right side posteriorly, and in the axillary line, were loose old adhesions; on the left side were firm old adhesions everywhere uniting the two pleural surfaces. There was no fluid on either side. In a few of the small branches of the pulmonary artery in the right lung were found hard white thrombi firmly adherent to the walls of vessels. Mucous membrane of bronchi was hyperæmic and covered with muco-pus. In the left lung was found a solid tumor at hilum, lobulated in outline, grayish yellow in color, of firm consistency, and measuring roughly two and three-fourths inches in diameter. It was sharply defined, both by its color and by its consistency, from the surrounding lung tissue. Lung tissue immediately about it was not well aërated. It involved bronchial glands. Beyond tumor bronchial tubes were considerably dilated. The primary bronchus can still be seen to pass through the tumor, its lumen being almost completely obliterated, and its walls being in some places infiltrated with tumor tissue, and in some places wholly made up of that tissue. Centre of tumor was broken down. Remote from tumor and scattered through lung were many small, hard masses varying in size from that of miliary tubercle to half of a small pea, whose color and consistency were exactly like that of the tumor itself. Lung generally felt tougher and less elastic than normal. Heart: Valves were normal; ventricles were dilated. In right ventricle were old, hard, white thrombi beneath and between columnæ corneæ, firmly adherent to endocardium, with softened centres. They were, like those in the pulmonary artery, evidently of ante-mortem formation. Spleen was large, soft, and congested. Kidneys were normal. Liver was normal in size. Centres of acini were atrophic and pigmented; peripheries were anæmic. Stomach, intestine, œsophagus, trachea, larynx, and brain were normal. On microscopic examination the tumor proved to be a carcinoma. In its older portions the alveoli are distinct and large, and filled with shapeless epithelial cells, and the fibrous stroma is abundant.

Multiple Cancellous Exostoses.—Dr. C. L. Dana showed photographs of a case, with the following history: The man, an Italian, aged thirty two, came into Bellevue Hospital suffering from rheumatism and presenting a number of exostoses, about twelve in all, in different parts of the body, mainly in the neighborhood of the epiphyses of the long bones. A very large one was on the sacrum, some were on the hands, etc. He said he had had the trouble since birth, whether others in the family had it could not be learned. The speaker referred to six cases reported by E. J. Maclean, *Bristol Medico Chirurgical Journal*, December, 1890, the patients being related as aunt, father, daughter, and three sons. The speaker's case confirmed the following points made by Maclean: 1. That the exostoses do not all originate from the neighborhood of epiphyses; 2. That in some instances they do originate thus, or from the usual sites of muscular attachment, or from both these positions; 3. That the bones of the face and spinal column (to palpation), the sternum and patellæ, are exempted, and the bones of the head almost so; while the long bones, scapulæ, and ribs are extensively affected; 4. That the pelvis (ilium) is affected (in three of the six cases of Maclean's.

Dr. V. P. Gibney recalled the case of a German who had come under his observation with a number of exostoses. His grandfather had also had similar bony tumors. One of his daughters, aged fourteen or fifteen, had half a dozen. One boy, who was a stupid fellow, had nine exostoses on the long bones, and it was a question whether there might not have been one on the inner surface of the skull. He had since become a confirmed idiot. There was one other child in the family who had one or two small exostoses on the tibia. Dr. Gibney said he happened to see another family thus affected about the same time the one just mentioned came under his observation, some years ago, but he had seen none since. The affection was very rare.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 23, 1891.

Orlando B. Goulas, M.D., President, in the Chair.

Local Therapeutics in Diseases of the Nose and Throat.—Dr. Wendell C. Phillips read a paper with the above title (see p. 422).

Peroxide of Hydrogen as a Disinfectant.—Dr. Paul Gibier, who had been quoted as to the disinfectant qualities of peroxide of hydrogen, said its power was due to the liberation of oxygen, which, under pressure, destroyed all forms of microbes. He was surprised this agent had not come into more general use as a disinfectant, but one reason was, doubtless, the great difficulty of obtaining it pure. Chemists would, probably, by their improved methods, overcome this difficulty.

Dr. James E. Nichols could not agree with the author in advising almost exclusive use of oil solutions in the nasal cavity. They did not come in close contact with the mucous membrane because of the watery osmosis beneath. But he did object, also, to alkaline solutions in hypertrophic rhinitis, as they served to increase the osmosis. While the first feeling after cleanliness was one of relief, reaction soon took place if they were continued. Having performed the necessary surgical operation, and cleansed with an alkaline or neutral solution, afterward use oily preparations. He also employed oily preparations in ozæna or chronic atrophic rhinitis. Carbolic acid in nasal sprays was an irritant, and should not be used. The patient should be cautious in blowing the nose after the use of the spray, etc., lest purulent matter be insufflated into the Eustachian tube and cause otitis media.

Dr. L. A. Coffin said that when a patient with catarrh came to him, he expressed confidence in his ability to benefit him only when he saw something which could be removed surgically. Having removed the apparent cause, he sent the patient home, and unless there were sepsis on his return, he usually did nothing more, and he found that he got much better results than formerly, when continually spraying, wiping, burning, etc. As to oily solutions in preference to the aqueous, it was true the former protected the mucous membrane, but they also thus prevented the mucous membrane from acting upon the inhaled atmosphere, and thus did harm. He had found peroxide of hydrogen a most excellent means to stop hemorrhage after operations. In order to get the plug out, use some cocaine, and it would almost fall out of itself.

Dr. Robert C. Miles thought the differences of opinion expressed were due largely to differences in diagnosis. Speaking of carbolic acid in vaseline, he said its effect was soothing. In hypertrophic rhinitis stimulants or irritants, as menthol and oil of mustard, should be avoided.

Dr. Wilbis, of Toledo, O., believed in the use of the petroleum products, but not all were adapted to the same case. For instance, after an operation he would use products which melted at a high temperature, say at 104° F., as protectives. But if one had a case of vasomotor disturbance, as in hay fever, he would use one of the petroleum products of a lower melting point. In hypertrophic rhinitis he would use one applicable by spray. The continued use of eucalyptol had a hardening influence upon the mucous membrane which lessened the predisposition to take cold, and to be affected by anything irritating.

The President suggested a trial of lanolin, either alone or mixed with vaseline, etc.

Dr. Phillips closed the discussion.

A Year's Report on the Therapeutics of Children's Diseases.—Dr. H. D. Chapin read a paper on this subject.

Experimental Research on Koch's Fluid, with Exhibition of Results of Culture and Effects upon Animals.—Dr. Paul Gibier read a brief paper with this title. He made experiments, first, on the bacillus tuberculosis; second, on animals; third, on three patients. The experiments made on cultures consisted, first, in mixing 1 milligr. with 5 c.c., afterward 1 milligr. with 1 c.c. of mixture of glycerine agar. This proportion of the lymph to the medium culture might seem very large, but it did not prevent the development of the bacilli on the medium culture. His experiments on animals had resulted as in those by Dujardin-Beaumetz, of Paris, and some others. He injected a guinea-pig with human tuberculosis in November. It developed rather slowly. One month afterward he began inoculations with the Koch lymph, and had increased it to 100 milligr., using this amount at different times. After having injected 15 milligr., which produced slight reaction, no further reaction took place. Some tuberculous ulcers developed, which the inoculations seemed to increase instead of decrease. The guinea-pig was in a fair way to die in a few days. The lungs were evidently filled with tubercular infiltrations. He had found that the bacilli of tuberculosis, mixed up with the pure lymph, could still develop after the lapse of twenty-six hours; consequently the lymph had no effect on the bacilli. As to the effects of the lymph on tuberculous patients, he left it for physicians of greater experience to decide.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 11, 1891.

H. M. Biggs, M.D., President, in the Chair.

Report of a Case of General Tuberculosis, Treated with Koch's Lymph, with Autopsy.—Dr. H. P. Loomis presented such a report. (See the Medical Record for March 7th, p. 282.)

The President said that this report emphasized the fact that the lymph had no power to prevent the development of miliary tuberculosis, nor did it cause any degenerative changes in the tubercular deposits. Several cases had been observed in which tubercular ulcers of the tongue developed in persons while undergoing the Koch treatment.

Dr. George C. Freeborn said that he was at present studying the results of an autopsy upon a case of epithelioma of the face which had been treated by these injections. Death occurred about ten days after the last injection, with all the symptoms of intense pulmonary congestion, and the autopsy showed that the lungs were greatly congested, and in addition, contained certain nodules the exact nature of which he had not yet positively determined. The other organs of the body presented the intense hyperæmia to which allusion had been made in the paper.

A Large Fibro-myoma.—Dr. Freeborn presented half of a uterus with a large fibro myoma which had been removed by Dr. Chambers, at the Woman's Hospital, from a married woman, aged thirty-four, who had never had children. The duration of this trouble was four and a half years. The operation performed was supra-pubic hysterectomy, and on making the abdominal incision the bladder was found at the level of the umbilicus, and the ovaries attached to the inner side of the mass. The mass removed was flattened, oval, with an ovoid projection from its superior surface. It weighed in the fresh state 5,270 grm. The vertical circumference was 79 ctm., and the transverse 63 ctm. An antero-posterior section through this mass showed that the large fibro-myoma, measuring 19 × 20 ctm. transversely, sprung from the posterior wall of the uterus, and in the centre of this mass was an area of fibro-cystic degeneration measuring 6 × 11 ctm. In what appeared to be the anterior wall of the uterus was a small myo-fibroma. The interesting feature in the case was the development of this large mass in the posterior wall of the uterus, which, in its rapid growth has pushed up all the pelvic organs. The remaining one-third of the elongated vagina was plainly visible in the specimen.

Dr. Eugene Hodenpyl presented specimens from a case of cirrhosis of the liver occurring in a young man, aged twenty-one, who had been intemperate for many years. He had suffered from dropsy, and had been tapped on several occasions. The autopsy showed a typical "hobnail" liver, with very advanced changes for one of his age. There was also the so-called "fleshy spleen," presenting evidences of chronic interstitial splenitis. The lungs had been somewhat compressed by the fluid in the abdominal cavity. The only evidences of tuberculosis in the body were some cheesy bronchial nodes, which, when stained, showed very few tubercle bacilli. The small intestine, from about the end of the duodenum to within about one foot of the ileo cæcal valve, was intensely congested and almost necrotic, due to a thrombosis of the portal vein, and branches of the superior mesenteric veins. He had noticed thrombi in this locality in several instances, but was unable to offer any explanation of it. In answer to a question from the President as to whether the thrombosis was probably recent, Dr. Hodenpyl said that there was nothing in the history pointing to intestinal trouble except an occasional diarrhœa, and he was of the opinion that this condition developed just before death, and was of no special significance. There were no hemorrhages into the bowel.

A Case of Hemorrhage into the Brain.—Dr. E. D. Fisher presented specimens from a man, aged forty-five, who had been admitted to the hospital as an alcoholic case, being at that time only partially unconscious, and having no paralysis, but on the contrary good muscular power. The pupils were at no time abnormal. He passed rapidly into profound coma, and died within twenty-four hours. At the autopsy, in addition to various contusions on the body and limbs, there were hemorrhages into the occipito-frontalis and left temporal muscles, with fissuring of both tables of the skull, from the occiput on both sides along the parietal region. The brain showed an extensive hemorrhage lying between the dura and the cortex, and a considerable contusion of the brain on the left side, involving the lower portion of the third frontal convolution, and the anterior portion of the temporal, with a portion of the parietal lobe in the region of the fissure of Sylvius.

The case was chiefly of interest as showing how little there was on which to base an accurate diagnosis, and hence the necessary uncertainty as to treatment. He thought the hemorrhage originated from the veins of the

[TAKEN FROM A TREATISE ON MEDICAL AND SURGICAL GYNÆCOLOGY BY
S. POZZI, M.D., NOW IN PRESS BY WM. WOOD & CO.]

pia, and was not due to any injury to the middle meningeal artery, because the hemorrhage was entirely subdural.

Pachymeningitis Hæmorrhagica.—Dr. Fisher also reported a case of this condition. This man had been brought to the hospital for intoxication, and his speech at that time, though thick, was not incoherent; on attempting to walk, he fell continually toward the left side. The pupils were equal. During the night he became unconscious, œdema of the lungs developed, and he died thirty-six hours after admission. There was no reason to suspect injury. Contrasting the symptoms presented in these two cases, one of marked contusion of the brain, and the other of simple compression, the similarity of the symptoms was remarkable, and even the condition of the pupils failed as an indication of cerebral compression.

In answer to a question as to the relation of the traumatism to the cause of death, Dr. Fisher said that he did not think there was ordinarily much connection between the two, for death occurred too soon after the injury to be due to suppuration or inflammation.

The President said that he had been much impressed with the frequency with which he had met with lesions in the under surface of the frontal, and the temporo-sphenoidal lobes, which may have been due to the injuries received years before. This was just the locality where laceration and contusion almost invariably occur as a result of traumatism, and hence it was the amount of hemorrhage and not the contusion which determined death. The hemorrhage usually came from laceration of the vessels of the cortex.

Dr. W. P. Northrup exhibited a slide showing a transverse section of the dura in a case of chronic pachymeningitis hæmorrhagica interna.

Chronic External Hydrocephalus.—Dr. Northrup said that, although he had seen many cases of ordinary chronic hydrocephalus, this was the first time he had met with the external form, although the text-books did not speak of it as rare. He exhibited a transverse section of the dura. At the time of his death, the child was ten months of age. It had been born after a normal labor, and when about five months of age, it was noticed to have a large head, and to keep the thumb turned into the palm. When admitted to the hospital, on August 25th, it was much emaciated, and the skin was leathery and wrinkled. The temperature was 98.5° F. In September the head began to enlarge very noticeably, the sutures were gaping, and the child grew stupid and fretful. At the autopsy, which was made by Dr. G. S. Lynde, about one pint of fluid of the color of Müller's fluid escaped on opening the skull, and there was a large quantity of old blood-clots over the entire dura, but mostly on the right side posteriorly. On stripping off a thin layer of tissue, the dura was left stained a yellowish color. The brain itself was normal, there being no distention or staining of the ventricles. The section shows pachymeningitis in the dura with the formation of new vessels, and a recent exudate of pus and fibrin. The fibrous layer of the dura was unchanged, and toward the free surface there was a narrow layer of old vessels with a new connective-tissue formation, which near the free margin became converted into a soft, pultaceous layer of pus and fibrin.

Dr. J. S. Thacher exhibited specimens, and reported the results of an autopsy upon a case which several surgeons, in consultation with a well-known neurologist, had diagnosticated as one of cortical inflammatory lesion of the right hemisphere of the brain. The patient was a girl, twelve years of age, who was undeveloped for her age. She had received some injury on the head on November 28th, and two weeks after this she began to suffer from left-side convulsions. At times there was a deviation of the optic axes to the left, and the left pupil was dilated. The temperature was very irregular, rising at times to 105° or 106° F.; the pulse was sometimes very rapid; the respiration was slow. The urine was examined once during life, with negative result; but at the autopsy the urine which was in the bladder contained much albumin and casts. The patient was subjected to the operation of trephining, and died about one hour after the operation.

It was interesting to note that the line drawn upon the scalp before the operation to determine the position of the fissure of Rolando, exactly corresponded with this fissure. No lesion of the brain could be found except that made at the time of the operation. The drainage-tube had pierced the right hemisphere and the right ventricle, and reached about one-quarter of an inch into its floor, piercing the caudate nucleus. The left ventricle of the heart was found hypertrophied. One kidney was small, irregular, and nodular, with patches looking like scar tissue; the cortex was somewhat thickened, and the markings were pale and indistinct. The other kidney was enlarged, and presented otherwise much the same appearance. The uterus was extremely small for a child of that age.

Dr. Thacher said that he had met with three other similar autopsies, in which no brain lesion could be found. In one, diabetes was the only cause of death found; in the second, there was possibly enough syphilitic disease of the blood-vessels to account for the cerebral symptoms; and in the third, that of a pistol-shot wound over the right eye, in which the surgeon had trephined at the back of the skull without finding the bullet, the autopsy showed that the bullet was lodged under the orbital plate of the frontal bone, and not in the brain.

Dr. Thacher also presented the brain from a man who had been run over and killed. The specimen showed atrophy of the pyramidal tract secondary to a lesion of the right hemisphere. There was apparently an old spot of softening involving the middle of the internal capsule, and the adjacent part of the lenticular nucleus. The degeneration of the pyramidal tract was seen very strikingly in the medulla and in the pons. There was another spot involving the anterior part of the lenticular nucleus. The patient had had, several years before, an attack of left hemiplegia, from which he recovered with the exception of some paresis of the left arm. This attack was explained by the lesion just noted.

Dr. Thacher also presented a brain showing a small spot of softening in the outer layer and posterior part of the lenticular nucleus, from an old cyst, associated with very marked atrophy of the pyramidal tract on that side, and of the optic thalamus.

The President exhibited a liver containing certain pale areas, which by their gross appearance had at first led him to make an erroneous diagnosis. The patient was a negro, aged fifty-three, who at the time of his admission had marked emphysema, and soon afterward developed an irregular temperature ranging between 100° F. and 102° F. No cause could be found for this temperature, which continued for three or four months. There was a gradual accumulation of fluid in the abdominal cavity, and he died suddenly from cerebral hemorrhage. The autopsy showed extensive emphysema, lesions of the mitral and aortic valves, extensive endarteritis, and ascites, in addition to the diseased liver which he presented. This liver was considerably enlarged, and its surface indistinctly nodular. On section, numerous light areas, which showed distinctly through the capsule, were found scattered all through the liver, and projected above the cut surface. He had considered them small multiple secondary new-growths, until a careful search failed to reveal a primary tumor. Microscopical examination showed these areas to be not new-growths but liver tissue, surrounded by dilated vessels and extensive fatty change.

Dr. H. P. Loomis said that he had seen light areas around central veins which presented a very similar appearance. Dr. Prudden had examined them with him, and they had come to the conclusion that at some time previous there had been a passive congestion of the liver with overdistention of the capillaries, and that, after this cause had disappeared, the areas supplied by these vessels remained anæmic.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE LUMLEIAN LECTURES AT THE COLLEGE OF PHYSICIANS—THE TREATMENT OF STRANGULATED HERNIA WHEN THE INTESTINE IS GANGRENOUS OR ULCERATED—THE PRESIDENCY OF THE ROYAL COLLEGE OF PHYSICIANS.

London, March 28, 1891.

In his second "Lumleian Lecture," after reviewing the symptoms of dilatation of the heart, Dr. Broadbent discussed at some length the prognosis in early and late stages of the affection. He first considered those cases in which the effects of cardiac dilatation were fully developed. The first element, he said, in the judgment to be formed would be the urgency of the symptoms, and special importance attached to two—nausea and loss of appetite, and sleeplessness—from the effects which they had on the patient's strength. Frequent vomiting was of grave import, not only because the patient did not get the benefit of the nourishment, but because it showed that the stasis in the abdominal circulation had reached a point which interfered seriously with the digestive secretions. Attacks of fainting and of extreme exhaustion, or of severe dyspnœa, were also very serious.

Dr. Broadbent remarked that it was not always when the dropsy was excessive that the condition of the patient was worst. From the late appearance or entire absence of dropsy in fatty degeneration of the heart, in aortic disease, and mitral stenosis, it appeared that a certain degree of pressure in the arterial system was required to co operate with the back pressure in the venous system for the full development of dropsical effusion. When the œdema remained moderate in amount while other symptoms, such as breathlessness, faintness, and muscular weakness—the latter especially—indicated great cardiac inefficiency, it might be because the left ventricle propelled the blood with very little force. Degeneration might be a factor in the case. A frequent, short, unsustained pulse and heart-beat, without much œdema, might thus indicate a graver condition than extreme dropsy. Long-continued, excessive frequency of the pulse was an unfavorable sign.

The urgency of the symptoms being about the same, a larger degree of dilatation added gravity to the prognosis, and it should be borne in mind that approximation of the first and second sounds was always a very serious indication. A good right-ventricle impulse was a favorable point, and the lecturer said it had always appeared to him that there was a greater margin for treatment when the liver was considerably enlarged.

When the symptoms and physical signs had been well weighed, the first question to be asked in view of prognosis was whether there had been any adequate exciting cause of the symptoms? If there had been recognizable over-exertion, or grave anxiety—any bodily or mental strain—or if there had been a chill, giving rise to bronchitis or other affection of the lungs, or deranging seriously the liver and digestive organs, it might be hoped that rest and treatment would undo the ill effects, and restore the balance. If, on the other hand, the symptoms had crept on gradually without traceable cause, and especially when due care had been exercised, and there had been no habitual error of regimen or neglect of bowels, the probabilities were that the symptoms were the outcome of conditions which could not be reversed—of radical inherent weakness of the heart. The previous mode of life, active or sedentary, careful or imprudent, and especially the habits with regard to alcoholic stimulants, would have a very important bearing on the probable issue of the attack, as would also the general soundness and the absence or existence of disease of any other important organs, especially of the kidneys and liver. The patient's cheerfulness, hopefulness, and courage under his sufferings or his despondency, would make powerfully for or against him, not only as direct influences, but because the state of mind was often an index of the state of the system. The family history was also of weight in prognosis. Few tendencies ran more strongly in families than those which were manifested in the heart and vascular system, whether to high arterial tension with the effects on the vessels and heart which followed, or to dilatation and weakness, or to degeneration. A prognosis, otherwise not unfavorable, might have to be instantly revised on learning that the father and an uncle or two, or a brother, had died at about the patient's age from heart disease. Finally, the response to treatment would speedily afford a prognostic indication of the utmost value.

The lecturer then spoke of the prognosis of cases in which the disease was at an early stage, and less serious consequences had been produced. As regarded physical signs, he said, the most important evidence would not be as to the actual size of the heart, but as to the strength remaining in its walls. A greatly dilated heart which was capable of giving a recognizable apex beat and fair impulse of right or left ventricle, was more to be trusted than one which had apparently undergone less change in its dimensions, but the movements of which could scarcely be felt at all. There was always a possibility that degeneration might enter into the causation of the symptoms. It was better, again, that the sounds should be strong than weak, spaced than approximated, and it was important that the second sound of the ventricles should be well marked. In his experience, irregularity of action was of less consequence than frequency, and he had learned not to attach serious importance to the regular alternation of a strong and weak heart, so long as there was no great frequency with it. The pulse was of importance chiefly as an indication of the vigor with which the blood was propelled into the arterial system. Dilatation of the heart presupposed high arterial tension at the time of its production, and it was a favorable sign that a certain degree of this tension persisted. When we found a short, small, low-tension pulse, unless this was the result of treatment, it meant that the heart had not sufficient strength to maintain the pressure in the arteries. The probability of improvement or of prolonged immunity from ulterior consequences would next depend on the general condition of the patient, on the soundness and nutritional vigor of his tissues and organs, and especially of his blood vessels; if he were weak and anæmic, on the cause and character of the impairment of health—whether it was inherent or accidental, whether, in effect, it was remediable or not. When the state of the heart and of the general health was attributable to alcoholic or other excesses, including the abuse of tobacco, to habits or conditions adverse to health, whether or not the patient was willing and able to renounce his self-indulgence and relinquish his vices, or alter his ways and surroundings. Considerations of this kind were of the utmost importance.

At the last meeting of the Medical and Chirurgical Society Mr. C. B. Lockwood read a paper on the "Treatment of Strangulated Hernia when the Intestine was Gangrenous or Ulcerated." His communication was based upon the analysis of cases collected from the records of St. Bartholomew's Hospital, which had been treated in the manner laid down by Sir William Lawrence, viz., "by a free incision of the mortified part in order to unload the distended intestinal canal; or, if the gut should have already given way, to divide freely the integument and sac, and to leave the subsequent process of cure entirely to nature" the stricture being also divided, if necessary, for the proper flow of fæces. Out of 35 cases 31 died, and of the four which recovered one had a fistula eight months after operation. M. Lockwood urged that primary resection and suture of the intestine would be preferable.

Mr. Bryant said he was struck with the high mortality. He thought one would be very likely to tear away the healthy from the gangrenous portion on trying to draw

the gut down to resect it; but the operation might be valuable in a few selected cases. In the old method, as described by Sir William Lawrence, he thought it might be advisable to push back the knuckle of intestine so as to leave as straight a road as possible afterward. It was a mistake to draw down the bowel.

Mr. Bennett said the treatment advocated was an ideal one, but scarcely practicable. It had been shown that in many of the cases there was no relief of the bowel even after it had been laid open, and resection would not remedy this.

Mr. Hulke said there should be as little manipulation as possible of the gut in these cases. He thought it a mistake to combine the operations of resection and radical cure, as, if the bowel should not unite, there would be no outlet for the extravasated matters.

Mr. Treves said that when Mr. Mitchell Banks had brought up the subject in 1885 at the Medical Society, everybody must have been struck with the remarkable differences of opinion then expressed. This was due, he suspected, to the fact that in any individual's experience these cases were comparatively rare. Mr. Treves then showed that the statistics of mortality between the old method and primary resection were not comparable, the cases of the latter being selected, whereas the cases of the old method were taken straight from the hospital records. In acute intestinal obstruction Mr. Treves thought the less that was done the better, as the patients were not dying of gangrene but of obstruction. He thought the best and simplest way was merely to open the sac, and divide the stricture so as to relieve the obstruction. If the intestine was gangrenous, it was best to bring it gently down and attach it by sutures to the abdominal wall, and then either to open the gut or to let it open itself.

Sir Andrew Clark has been re-elected as President of the Royal College of Physicians.

NOT SO BAD AS IT SEEMS.

To the Editor of the Medical Record.

Sir: Is not "Justice" himself a bit to blame? Does he not, by betraying his irritation too plainly, give his patients the idea that it is jealousy at the success of the other man or the loss of business which prompts his indignation?

No one can condemn underhand methods more than I do, and I consider myself to have suffered from them in rare instances, yet when I have lost business in that manner have rather looked over my own armor to see where it was amiss and thus permitted the poisoned shaft to enter.

In the first place it is probably the case, nine times out of ten, that it is the officious friend who is unfair and not the brother practitioner. Secondly, the timid and anxious inquiries or suggestions of the patient are "sat down upon" too dogmatically. Thirdly, if one is sure that he is doing right and acting honestly, he can afford to be patient, trusting that the dishonest man will overreach himself, and then his patient will return with added confidence, never to stray again, provided that he has not, in his irritation, so offended that patient's self love as to render future intercourse impossible.

I have frequently lost the practice of families, but never failed to regain it if I did not allow myself to get angry. If I was even more pleasant than before, if I never failed to inquire after their welfare, if I uniformly preserved an appearance of well-being, showing that I was not angry at their changing doctors, that my practice did not immediately collapse because of their defection, and that I was honestly glad that the new doctor pulled them through all right, when he "slops over," as he is bound to do if he has acted dishonorably, they instinctively turn to the old friend who still is friendly.

Doctors there are who have thought it worth while to have looked up homœopathic methods of practice and have sifted out some wheat from a great deal of chaff, perhaps, and are willing to practice "both ways," or either way, if the good of the patient can be thereby secured, and in so doing are neither disreputable nor dishonest. "Justice" can, without stultifying himself, refrain from launching out in a tirade against homœopaths and honestly state that he believes in doing the best thing possible for the patient, and that he does not care whether he gives large or small doses provided he attains the end sought for.

Honesty, tact, and patience will win the battle in the long run. Finally, he must remember that even "blighted ovums" have a right to exist, so far as their imperfect development will allow of. Tact.

Gloversville, N. Y., March 17, 1891.

WAS IT ENTERIC FEVER?

To the Editor of the Medical Record.

Sir: In your issue of March 21, 1891, a case is reported of "Enteric Fever with Peculiarities," in which there was an even division in the diagnosis, two were for typhus fever, and two for typhoid fever. The compressed history of the case was as follows:

Female, aged fifty, was indisposed and exhausted; with headache, pain in the back and limbs; chilliness, distinct chill lasting about six hours in the second night, followed by fever, but no perspiration.

Third day: Temperature 103°F.; a rapid, compressible pulse; dry, furred tongue; nausea, inability to keep anything on stomach; bowels constipated; no abdominal symptoms; voiding a plenty of urine, febrile in character; face somewhat turgid; pupils contracted; mental condition rather sluggish; complains of splitting pain in the head, extending down spine; legs feel heavy and dead; staggers in attempting to get out of bed; irritable. Fever continues for days at and above 103° F., but never goes over 104° F.

Seven days from the commencement of her illness an eruption appears on her chest and abdomen of two varieties. One irregular in form, purplish, seemingly not elevated, disappearing on firm pressure, quickly returning, these spots are quite numerous, varied in size from a pin's head to a spot half as large as a penny (small?). seemingly formed by a coalescence of several smaller ones.

The second variety consisted of very small bright-red spots, which filled in the spaces between the others, and these were mainly on the abdomen, not elevated, disappeared on pressure, recurred slowly. These eruptions did not appear and disappear, but were continuous. She recovered in three weeks.

Are not most of the above symptoms classical of sporadic cerebro-spinal meningitis, with probable latent pneumonia?

As no mention is made of the condition of the lungs, the prolonged night chill is suspicious. This case commenced on January 19, 1891, and in this Journal there were reported for the week ending January 10, 1891, three cases of cerebro spinal meningitis, and five deaths. Doubtless the misleading factor with two of the doctors was the eruption of pseudo typhus.

It is unfortunate that so much stress is laid upon the diagnostic value of the so called rose spots, and also on the eruption of typhus fever. Typhoid fever, before its extinction in America, may be undergoing a change in its symptoms. And we may have a modified form of typhus fever in America, as we have American gout.

Certainly in places in America we have the majority of the predisposing elements that are had in Ireland, its frequent home. These eruptions are so liable to be wrongly described according as the observer is more or less conversant with skin diseases. As in painting, the eye has to be taught to see. The spots of typhoid fever are by no means invariably present, and are observed more

frequently in some years than in others, are not so often seen in the country, and are often absent in children.

I venture to say that a spot or spots of some kind can be found on the abdomen, chest, sides, or back of the average well man; none of us is "without spot or blemish." And he will sometimes be a very disagreeable doctor who in his ardor to find this *sine qua non* in diagnosis, rolls his feverish patient, as if he were a log, from side to side in the fervent hope and expectation of discovering one little petechia, or fleabite like spot. But he must be scientific, and the books tell him that when the spots cannot be found in front, look elsewhere, and after a certain number of days he will most certainly find a spot or spots, if the case is to be called typhoid fever, and he gives a mental eureka! provided he goes over sufficient territory, has good eyes, or a roseate imagination.

Concerning the diagnosis of typhoid fever made by two of the gentlemen, I would suggest that the patient's age, fifty years, and most of the symptoms, except certain mental symptoms, and the spots "appropriated" by them, were not diagnostic of typhoid fever.

THOMAS R. EVANS, M.D.

LINCOLN, VA., March 24, 1891.

THE EPIDEMIC OF LA GRIPPE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I read your able editorial on Grippe with great interest. It has been again prevalent in this city for some months; and it is reported to be severe in Chicago, with unusual fatality. There seems to be no concise and definite treatment decided upon—some physicians relying upon phenacetine or antipyrine, others giving quinine, or salicylate of cinchonidine, etc.

I have seldom or ever had occasion to visit anyone with this disease more than from three to five days, using the following method. As in yellow fever, a mercurial purge is required at the inception of the attacks—the following formula being used:

℞. Calomel ..... gr. iij.
Rhubarb ..... gr. iv.
Calc. magnesia ..... gr. xx.
Soda ..... gr. iij.
Ipecac ..... gr. ½.

And if fever exists, a fever mixture:

℞. Spirits of mindererus ..... ʒ j.
Sweet spirits of nitre ..... ʒ iij.
Tincture of aconite ..... gtt. xxx
Paregoric ..... ʒ ij.
Water to ..... ʒ iv.

A dessert-spoonful in water every two hours.

If, as is often the case, the lungs threaten to become implicated, wine of antimony and syrup of senega, āā ʒ iij. are added; with the use of local applications to the chest, or to the seat of pain, of mustard or turpentine.

Three grains of quinine are given thrice a day, and port wine freely used, after the first day. I prefer California port because it is sound and inexpensive. Milk punch may also be used, as it prevents the tendency to weakness and prostration. If there is much pain, headache, or insomnia, phenacetine, five to seven grains, can be prescribed for their relief, preferably at night.

In a youth, who we saw with his father, a physician, and who was suffering from a relapse, the high and persistent fever, and repeated and violent delirium—occurring day and night—were completely relieved by five grains of phenacetine given twice at an interval of six hours.

As soon as the purgative produces a medicinal effect, the force of the disease seems to be broken. Antimony is to be preferred to ipecacuanha to prevent the tendency to pneumonia or to congestion of the lungs.

CHARLESTON, S. C. F. PEYRE PORCHER, M.D.

"**Make Somebody Else Happy**," was the prescription given by a wise physician to a victim of nervous depression.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 4, 1891.

	Cases.	Deaths.
Typhus fever	1	0
Typhoid fever	8	8
Scarlet fever	225	25
Cerebro-spinal meningitis	4	5
Measles	386	22
Diphtheria	101	31
Small-pox	0	0
Varicella	5	0
Pertussis	7	13
Erysipelas	1	0
Mumps	0	0
Rötheln	0	0

Ichthyol.—The addition of ten per cent. of oil of citronella is said effectually to mask the odor of ichthyol, while in no way detracting from its therapeutic virtues.

Vinegar for Urticaria.—After trying many remedies in a severe case of urticaria Mr. Swain found a vinegar lotion gave almost instant relief, and subsequent trials in other cases have been equally successful. One part of water to two parts of vinegar is the strength most suitable.—*British Medical Journal.*

For the Prevention of Baldness.—It is recommended for the prevention of baldness that the hair be kept pretty closely cropped, and that the head be bathed frequently in salt water and lubricated occasionally with a very small quantity of vaseline. About two teaspoonfuls of salt to a pint of water will make a tonic of the proper strength, and with this the head should be bathed at least three times a week.

An Ingenious Way of Putting It.—A lecturer in a popular medical college is reported to have made the following bid for consultations at the close of one of his lectures: "If the public presumes to attack the professional characters of men who are your medical teachers, how careful you should be in all important cases to guard yourselves by calling in older and more experienced advice—and by getting the responsibility shared."

Cholera in Calcutta.—During the four weeks ending January 3, 1891, there were one hundred and thirty-two deaths from cholera in Calcutta.

STUDIES ON THE ETIOLOGY OF DIPHTHERIA—SECOND SERIES.

BY T. MITCHELL PRUDDEN, M.D.,

DIRECTOR OF THE LABORATORY OF THE ALUMNI ASSOCIATION, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

IN an experimental study on the etiology of diphtheria, published by the writer in 1889,[1] a brief summary was given of the more important bacteriological studies which had been made of this disease, up to that time, by the new methods in various countries. This summary showed that the attention of the observers had been largely centred on two species of bacteria, which, sometimes apart, sometimes together, had been so frequently found in the pseudo membranes as to give rise to a justifiable belief that one or other or both of them might be the cause of the disease. These bacteria were the so-called Bacillus diphtheriæ of Loeffler, and a streptococcus which most observers are inclined to believe identical with the Streptococcus pyogenes and Streptococcus erysipelatos. The evidence which had accumulated along these lines was largely such as was derived from the presence of these germs in the local lesion or elsewhere in the bodies of the victims of diphtheria. The results of animal experiments were in so far indecisive as that, while they showed that both forms of bacteria were in different ways pathogenic, neither of them was capable of inducing a disease which could be fairly considered absolutely identical with human diphtheria. The animal experiments with the Bacillus diphtheriæ were by far the most convincing in this regard, inasmuch as with this germ a pellicle somewhat analogous to the pseudo-membrane of diphtheria could be produced by their application to a wounded mucous membrane, and in some animals, notably the guinea-pig, death regularly followed subcutaneous injections of cultures, with definite and fairly constant lesions. The lack of precision in our conception of what should be called, strictly speaking, diphtheria, and what forms of disease associated with the development of a pseudo-membrane, if any, should be held apart from it, has led to much uncertainty as to the interpretation of the results of all these studies. Clinical observers in this country have been disposed of late—erring, if erring at all, on the side of safety—to consider and to treat all pseudo membranous inflammations as if they were the local expression of the acute infectious disease which has been called diphtheria.

This condition of affairs, however, wise as its perpetuation might seem to be from the practical standpoint of the bedside adviser, is most confusing and unfortunate from the point of view of the seeker after the primary causes of all these phases of pseudo-membrane inflammation, because it is fully established that a pseudo-membranous inflammation of the mucous membranes may be induced by a variety of agents.

As the result of a summary made in the paper above alluded to, in 1889, of the cases from which the bacillus of Loeffler had been isolated by culture, and its virulence proved by animal inoculations, it was found that this bacillus had been cultivated from 24 out of 28 cases, thus far fully studied.[1] Fuller reports of studies not included in the above summary on account of too meagre details then at hand, and studies made since that time, which have been numerous and important, show the following results so far as the bacillus of Loeffler is concerned:

Babes[2] found the Bacillus diphtheriæ in all of 42 cases of diphtheria; D'Espine[3] found it in 14 cases; Ortmann[4] in 15 out of 16 cases; Spronk, Wintgens and Van den Brink[5] in all of 7 cases; Roux and Yersin[6] in all of 15 cases; Kolisko and Paltauf[7] in 50 cases; Zarniko[8] in 18 out of 20 cases; Beck[9] in 50 out of 52 cases; Sörensen[10] in 7 out of 10 cases; Escherich[11] in 20 out of 22 cases; Tangl[12] in all of 18 cases; Brieger and Fraenkel[13] in all of 22 cases.

We have thus on record at the present time, so far as the literature is available to the writer, the results of the examination of 316 cases of so-called diphtheria, in 302 of which the bacillus of Loeffler was found.

A large number of control examinations by various observers have established the fact that this virulent bacillus is rarely, if ever, found in the body except in the local lesion of diphtheria, and is almost never present in any other disease or in health. A so-called pseudo-diphtheria bacillus has been found both in the membrane of diphtheria and in healthy or otherwise diseased individuals. This bacillus is morphologically, as well as biologically, similar to, if not identical with, the Bacillus diphtheriæ, but is not virulent on inoculation into guinea-pigs or the commonly employed animals.

Very significant experiments on animals with a poison developed in the cultures of the Loeffler bacillus, a poison capable of inducing delayed paralyses and other toxic symptoms,[14] as well as various other collateral studies which cannot be considered here, serve to reinforce the evidence now at hand, that the Bacillus diphtheriæ of Loeffler is the causative agent, in a large proportion of cases at least, of the disease commonly spoken of as diphtheria.

On the other hand, a large proportion of the observers who have found the Loeffler bacillus in the pseudo-membranes of diphtheria, have found more or less frequently associated with it a streptococcus apparently identical with the Streptococcus pyogenes and Streptococcus erysipelatos. Furthermore, there is recorded a considerable number of cases of pseudo-membranous inflammation closely simulating, if not identical morphologically and clinically, with diphtheria, in which not only is the Bacillus diphtheriæ of Loeffler absent, but in which the above-mentioned streptococcus is nearly constantly present. These forms of so-called diphtheria are most commonly associated with scarlatina and measles, erysipelas and

phlegmonous inflammation, or occur in individuals exposed to these diseases; but whether exclusively under these conditions, is not yet fully established.

Thus Loeffler [1] says as the result of his work: "That the chain-forming micrococcus can cause a disease similar to diphtheria when it enters the pharynx and spreads toward the lungs in the tracheal lymph-channels, I consider very probable." Fraenkel [2] found a streptococcus in nearly pure culture in two cases of somewhat atypical diphtheria; Raskin [3] found a streptococcus, but not the Loeffler bacillus, in two out of three cases of so-called scarlatinal diphtheria. In a series of cases of scarlatinal diphtheria studied by Heubner [4] the bacillus of Loeffler was wholly absent, but a streptococcus was always present. Wurz and Bourges [5] found in nine cases of scarlatina, in which the diphtheritic lesion developed early, that the bacillus of Loeffler was absent, while a streptococcus similar, but, according to them, not absolutely identical with the Streptococcus pyogenes, was present in all. In two cases in which the diphtheritic lesion developed late, the bacillus of Loeffler was found. Roux and Yersin,[6] in three cases supposed clinically to be diphtheritic from the development of a pseudo-membrance on and behind the tonsil, and in one case on the tongue and lips, failed to find the Bacillus diphtheriæ (Loeffler), but did find cocci, in two of the cases of well-marked streptococcus form.

Chantemesse and Widal have reported cases in which a fibrinous exudate similar to that of diphtheria was associated with a streptococcus.

In the series of studies of 24 cases by the writer in 1889, already alluded to, the bacillus of Loeffler was absent in all, but a streptococcus apparently identical with the Streptococcus pyogenes was found in 22. This result, negative, so far as Loeffler's bacillus is concerned, has seemed to excite dissatisfaction among many of the German reviewers of the article, since it has been interpreted by them as speaking against the etiological importance of Loeffler's bacillus, an interpretation which was not drawn by the writer in the article in question, and which seems to him wholly unjustifiable.

In view of the doubt existing among practitioners as to whether all forms of pseudo-membranous inflammation should be called diphtheria, or not, and with the purpose of making a wholly objective study, the writer distinctly stated at the outset of that paper, that all the fatal cases of extensive pseudo-membranous laryngitis, as well as pharyngitis, should in his study be considered as cases of diphtheria. This left the question as to the propriety of establishing separate groups of pseudo-membranous inflammation open and free from bias. It was distinctly stated, however, that 16 out of the 24 cases occurred in a large asylum, in which measles and scarlatina were prevalent during the period in which these studies were under way. Five other cases from another asylum were exposed to similar conditions. Furthermore, it is set forth in the clinical histories of the individual cases, that 2 were associated with whooping-cough, 2 with umbilical phlegmon, 1 with chicken-pox, 2 with scarlatina, 1 with rectal abscess, 1 with erysipelas of the vulva, 4 with measles. While no such complications existed in the individual, in the remaining ten cases, the fact that they were largely (all but two) children intimately associated with those exhibiting one or other of the complicating disorders, was not perhaps sufficiently emphasized, but seemed to the writer so patent from his preliminary statements, that it was not deemed necessary to call specific attention to it.

We should not forget that there is a very significant possibility that sensitive children closely associated in nursery wards with others suffering from scarlatina, measles, and erysipelas may, though not actually affected with these diseases themselves, still be liable to acquire those complicating forms of disease which find expression in a pseudo-membranous pharyngitis and laryngitis.

In the conclusions which were drawn from the results of these examinations, the writer stated that, "It should be distinctly understood that these studies on the etiology of diphtheria, and the conclusions derived from them, apply only to a certain set of cases. It by no means follows that because this particular group of cases of diphtheria is caused by a streptococcus, and seems to be intimately related in etiology to some other common phase of inflammation, that all cases of diphtheria are induced by the same organism, or are related in the same way to erysipelas and phlegmon."

That other organisms than the streptococcus here described may induce that set of symptoms and lesions to which we give the name diphtheria, we must, of course, admit, and this the more readily on account of the great variability of both symptoms and lesions in even well-marked groups of cases. So far as Loeffler's experiments go, they tend to indicate that some other forms of bacteria really may play a part in the induction of certain forms of the disease." And further, "On the whole, it seems to me that, considering the insusceptibility of animals to diphtheria as we know it in man, the result of all these series of experiments taken together, abundantly justifies us in the assumption that in a certain class of cases, at least, diphtheria is caused by a streptococcus having the character set forth above."

In view of the apparent discrepancy between the results taken as a whole, and those of other observers, the writer has been over the material which served as the basis of these researches, so far as it was still available, and fails to find any reason for a revision of his results or his conclusions.

Of course, one would not for a moment deny the possibility of the Loeffler bacillus having been overlooked in some of these cases, since the experimental error is not inconsiderable in all studies of this kind. Here a negative result is, however, never of equal weight with a positive one. But the extremest care was used, and I do not think there was any oversight. It is furthermore not beyond the bounds of possibility, as Baumgarten [1] suggests, that the Loeffler bacillus may lose its vitality early in the presence of large numbers of other bacteria, such as the streptococci, and so may not be revealed in the cultures.

It has been suggested, and upon this point much stress has been laid, that the culture medium largely employed by the writer for the plate cultures, namely, glycerine-agar, is not as favorable for the purpose as is the blood-serum mixture employed and recommended by Loeffler, since on it, the growth of the Loeffler bacillus is not so rapid in comparison with that of other bacteria. That it is sufficiently well adapted to this purpose, to say the least, is shown by its recommendation and employment by several reliable observers, and by the fact that the writer has found no difficulty in separating by its use the Loeffler bacillus in cases of diphtheria in which that germ was present, as it was in most of the new series of cases presently to be described. Glycerine-agar (six per cent. glycerine) is a perfectly good and wholly reliable medium for the cultivation of the Bacillus diphtheriæ of Loeffler, and for its separation from other forms of bacteria which may be present in the various forms of pseudo-membrane. But to be successful with this medium, it is wise, as was always done in the experiments in question, to make numerous plates, and to make the streaks upon the agar on these plates so dilute and so numerous that the Loeffler bacillus will have the opportunity when present to grow sufficiently for recognition and resowing in some places at least without overgrowth by, or interference with, other forms of germs.

The whole, or at least the main, difficulty in this matter

[1] Baumgarten: Jahresbericht über die Fortschritte in der Lehre von den pathogenen Mikroorganismen, 1889, p. 215.

seems to the writer to be one not of technique, not of imperfect observation, but one first of nomenclature, and second of premature assumption as to the unity of cause in pseudo-membranous inflammations. In other words, in order to decide positively what causes diphtheria, we need to know positively what symptoms or lesions shall be recognized as characterizing it, in distinction from other allied symptoms and lesions, if such exist, which are of different nature and different origin. If we cannot determine this at the bedside, we must strive by the new biological methods to gain such knowledge of the etiology of the whole group as shall enable us to decide whether or not it should be divided into separate classes.

In view of the condition of affairs at present existing, and as it did not seem at all probable that the disease properly called diphtheria could have a specific bacterial cause different in America from that known in Europe, it has seemed incumbent on the writer to undertake a new series of studies on a set of cases from which the complicating conditions existing in most of the previous cases should be so far as possible eliminated.

The cases now to be recorded, twelve in number,[1] were cases of fatal pseudo-membranous inflammation occurring in two children's asylums, in which for many months there had been no scarlatina and no measles, and in which there were no complicating suppurative inflammations and no erysipelas. In one case only was there the complication of whooping-cough.

The following are the cases and the results of their examination :

Case I. *Clinical History.*—Female, three and one-half years of age. September 22, 1890, pharyngeal pseudo-membrane. September 24th, laryngeal symptoms. September 25th, 5 A.M., intubation, followed by rise of temperature, 108° F. ; died at 12 P.M., cyanotic.

Autopsy.—A dense, firm, closely adherent membrane on both tonsils, on posterior surface of epiglottis, and extending throughout larynx and trachea down to medium bronchi ; loosened and thinner below. Lungs : deep congestion with broncho pneumonia in both posterior lobes. Kidneys : parenchymatous degeneration.

Bacterial Examination, Morphological. — Moderate numbers of stout bacilli in older parts of pseudo-membrane, with considerable numbers of cocci in masses and scattered.

Cultures. — Membrane, the most abundant colonies showed the characteristic mode of growth of the Bacillus diphtheriæ (Loeffler) on the plates and in tube-cultures of glycerine-agar, gelatin, and beef-tea ; stained specimens from these cultures showed the characteristic bizarre form. I do not give a detailed description of the morphology and biology of these bacilli, since no new observations were made on them and they corresponded in all respects with the well known and definite descriptions so often reported. Almost equally abundant were colonies, cultures from which gave the characters of Streptococcus pyogenes. There were also numerous colonies of Staphylococcus pyogenes aureus, and a few scattering forms, mostly bacilli. Cultures from the kidneys were negative.

Animal Experiments.—Inoculation of the sediment of beef-tea cultures four days old of the bacillus resembling the bacillus of Loeffler into a guinea-pig, was followed by death within thirty-six hours, with hemorrhagic œdema, and a localized whitish exudate at the seat of injection ; effusion into the serous cavities, and a moderately swollen spleen. Cultivations from these animals gave pure cultures of Loeffler's bacillus from the exudate at the seat of inoculation, and no growth whatsoever from the heart's blood and viscera.

[1] A large part of the material used in this study came from the New York Infant Asylum, Mount Vernon, N. Y., from the service of Dr. Robert Millbank. For this material and for his most valuable collaboration in other ways, I wish to express my indebtedness to Dr. Charles G. Kerley, Resident Physician of the New York Infant Asylum. The remainder came from the New York Foundling Asylum, and for this I am indebted to Dr. Wm. P. Northrup and Dr. G. S. Lynde.

Remarks.—This child was quarantined with several other children before it became ill, and developed its disease at the same time as another child, and there were three more cases in the same building immediately following these.

Case II. *Clinical History.*—Female, aged three years and ten months. January 5, 1891, membrane seen on pharynx and continued there, with an unusual amount of white membrane forming in pharynx and nose. January 16th, intubated, and much membrane coughed up. January 21st, suddenly grew much worse, with heart failure ; rallied twice, but dropped dead at 6 P.M.

Autopsy.—Loosening membrane from tip of epiglottis down into medium bronchi. Lungs : broncho-pneumonia in middle and upper lobe posteriorly. Kidneys : parenchymatous degeneration.

Bacterial Examination, Morphological.—Large numbers of cocci massed and scattered in pseudo-membrane ; no bacilli found.

Cultures.—Membrane, large numbers of colonies of streptococcus having the characters of Streptococcus pyogenes developed on the plates from the pseudo membrane ; also considerable numbers of Staphylococcus pyogenes aureus. The bacillus of Loeffler did not develop on any of the plates. Cultures from the lungs and from the kidneys showed considerable numbers of Streptococcus pyogenes and Staphylococcus pyogenes aureus and nothing else.

Remarks.—This case had not, so far as known, been exposed to diphtheria, and there were no cases in the nursery for three months previously.

Case III.—Male, aged two years and ten months. February 1, 1891, croupy in the evening ; membrane over pharynx. February 2d, severe dyspnœa ; intubation. February 3d, albumin in urine ; temperature, 104° F. ; cyanotic ; no evidence of pneumonia. February 4th, died.

Autopsy.—Dense membrane on tonsils and in larynx and trachea down to first bronchi. No pneumonia ; parenchymatous degeneration of kidneys.

Bacterial Examination, Morphological.—Large numbers of bacilli, single and clustered in the more superficial part of the pseudo-membrane ; also large masses of cocci, single and in chains.

Cultures.—Membrane, moderate numbers of colonies resembling on the plates and in subsequent tube cultures, the Bacillus diphtheriæ (Loeffler), enormous numbers of colonies of Streptococcus pyogenes, considerable numbers of colonies of Staphylococcus pyogenes aureus. Lung cultures contained a few colonies of Loeffler's bacillus, many streptococci, and a few staphylococci. Kidney cultures were negative.

Animal Experiments.—A guinea pig inoculated subcutaneously with the sediment of a four-days old beef-tea culture of the Loeffler's bacillus, died thirty-six hours after, with the usual local lesions, cultures from which showed the specific bacillus, while visceral and blood cultures were negative.

Remarks.—There had been no diphtheria in the nursery for at least two months before this child was attacked.

Case IV.—Female, aged two years and eight months. Had whooping-cough and a broncho-pneumonia early in January, 1891, which ran a short course ; was exposed to diphtheria late in January. February 1st, croupy ; temperature 102° F., with loose patches of exudate on tonsils ; might from appearance have been called follicular tonsillitis. February 2d, temperature, 102° F. to 104° F. ; intubation. February 7th, evidence of lung consolidation left posterior. February 8th, tube removed ; continued growing worse. February 11th, died. The whooping cough continued throughout the course of the diphtheria.

Autopsy.—Moderate membrane, loosened and disintegrating and peeling off below from epiglottis to larger bronchi. Moderate amount of broncho-pneumonia and congestion in posterior lobes of lungs.

Bacterial Examination, Morphological.—Found no bacilli in the loose shreds of membrane still adhering to surface, but these, as well as the superficial layer of the mucosa, showed many cocci single and in masses.

Cultures.—From the membrane there developed on the plates very large numbers of characteristic colonies of the Bacillus diphtheriæ (Loeffler), characteristic also in tube cultures. Also large number of colonies of Streptococcus pyogenes and a moderate number of Staphylococcus pyogenes aureus. From the lungs grew on the plates many streptococci and a few staphylococci.

Animal Experiments.—A guinea-pig inoculated subcutaneously with the sediment of a five days old beef-tea culture of the Loeffler bacillus, died on the second day with the characteristic lesions, and gave positive cultures from seat of inoculation, negative from blood and viscera.

Case V.—Female, aged twenty one days; good condition at birth. February 17th, sick. February 18th, cyanotic with extreme laryngeal obstruction. No membrane visible; epiglottis not swollen; temperature 102½° F. Intubation; large piece of membrane coughed up, with considerable relief. February 19th, cyanotic; collapse; death.

Autopsy.—Pharynx normal; no distinct membrane in air-passages, but a turbid adhesive exudate in larynx and trachea. Broncho-pneumonia posteriorly, with congestion and punctate hemorrhages. Kidneys, spleen, and liver appear normal.

Bacterial Examination, Morphological.—No bacilli found; moderate numbers of cocci, single and clustered and in chains, penetrating the mucosa in the larynx.

Cultures.—From the scrapings of trachea and larger bronchi there developed on the plates a few colonies characteristic of the Bacillus diphtheriæ (Loeffler); very many of Streptococcus pyogenes and many of Staphylococcus pyogenes aureus. The lung contained, as shown by cultures, enormous numbers of Streptococcus pyogenes, and a few of Staphylococcus pyogenes aureus. On the kidney plates developed many streptococcus colonies. From the spleen and liver nothing grew.

Animal Experiments.—Large guinea-pig inoculated subcutaneously with sediment of beef tea culture of the Loeffler bacillus died in thirty-six to forty eight hours, showing characteristic lesions, with the specific germs only at the seat of inoculation.

Case VI.—Male; aged one month, eight days. On February 19th, came into hospital with bad naso pharyngeal diphtheria. Membrane reformed with great rapidity if removed. Broncho-pneumonia developed. Death, February 22d.

Autopsy.—Dense, tough, closely adherent patches of pseudo-membrane in the pharynx and about base of epiglottis, a small amount in the upper part of the larynx; none below. Lungs, dense; broncho-pneumonia posteriorly. Kidneys: marked parenchymatous degeneration. Liver, congested. Spleen soft and slightly enlarged.

Bacterial Examination, Morphological.—Large numbers of bacilli in masses in the superficial parts of the pseudo-membrane; also numerous cocci, but slightly penetrating.

Cultures.—From the pseudo-membrane in pharynx developed an enormous number of colonies characteristic of the Bacillus diphtheriæ (Loeffler); large numbers of Streptococcus pyogenes, and many of Staphylococcus pyogenes aureus.

Lung plates showed a nearly pure culture of enormous numbers of streptococci and a few of the staphylococcus. From the liver and spleen developed considerable numbers of streptococci and nothing else, while the kidney cultures were negative.

Animal Experiments.—A large guinea-pig inoculated with sediment of a four days old beef tea culture died on the eighth day, showing the typical local lesion, with the Loeffler bacillus present at seat of inoculation, and nowhere else. A second animal, inoculated with a three days old culture, died on the second day with typical local lesion.

Case VII.—Male, aged twenty-three months. January 9th, tonsils swollen and congested; pharynx and fauces congested. January 10th, croupy, with laryngeal obstruction; hoarseness; dyspnœa; prostration and increasing cyanosis; râles over chest; temperature, 102° to 104° F.; no exudation visible; intubation, which gave marked relief. January 11th, respiration frequent; congestion and swelling of tonsils continues, but no exudate visible; prostration. Failed and died 5.15 P.M.

Autopsy.—Moderately dense and voluminous membrane from tip of epiglottis down to bifurcation of trachea, and extending on right side to finer bronchi, on the left into first divisions. Broncho-pneumonia in both lower lobes, and middle right vesicular emphysema.

Bacterial Examination, Morphological.—Small numbers, clustered and scattered, of short, rather stout bacilli, and few cocci in pseudo-membrane.

Cultures.—Large numbers of colonies on plate with characteristics here and in subsequent tube cultures of the Bacillus diphtheriæ (Loeffler), considerable numbers of Streptococcus pyogenes, and a few Staphylococcus pyogenes aureus.

Animal Experiments.—Large guinea-pig inoculated subcutaneously with sediment of five days old beef-tea culture of the Loeffler bacillus, died on third day with characteristic lesions, cultures showing the specific bacillus at seat of injection, but nowhere else.

Case VIII.—Female, aged fifteen and one-half months. January 12th, cervical lymph-nodes and tonsils swollen; fauces and pharynx congested; temperature, 100° F. January 13th, breathing labored; prostration; intubation; temperature, 104° F. January 14th, thick granular exudate scattered over tonsils and palate; breathing labored; temperature, 105° F. January 15th, temperature, 104½° F.; died at 3 P.M., after two convulsive seizures.

Autopsy.—From tip of epiglottis to middle of trachea, shreds of membrane loosely adherent. Dense membrane from middle of trachea down into finer ramifications of bronchi. Broncho-pneumonia in posterior part of both lower lobes; vesicular emphysema. Kidneys showed parenchymatous degeneration, as did liver. Spleen slightly enlarged and soft.

Bacterial Examination, Morphological.—Moderate numbers of stout, short bacilli in pseudo-membrane.

Cultures.—Large numbers of colonies of Bacillus diphtheriæ (Loeffler). A small number of Staphylococcus pyogenes, and a considerable number of a slender short bacillus (not identified).

Animal Experiments.—A large guinea-pig injected subcutaneously with sediment of a three days old beef-tea culture of the Loeffler bacillus, died on the third day with characteristic lesions, and localization of the germs to seat of injection.

Case IX.—Female, aged eleven and one-half months. January 7th, spot on left tonsil size of flaxseed; temperature, 103° F. January 8th, thick, yellow, cheesy exudate on both tonsils, size of split pea; restless; cough; temperature, 104½° F. After this the tonsils cleared, and the temperature went down to 99° F., 100° F., then the exudate reappeared; child was hoarse and croupy with pulmonary obstruction, with temperature 104½° F. on January 16th and 17th; prostration and cyanosis supervened; pharyngeal exudate increased; pneumonia developed; temperature between 103° F. and 104° F., with death on January 20th.

Autopsy.—Membrane extending from tip of epiglottis to smaller bronchi; pneumonia of both lungs.

Bacterial Examination.—This was made from a fragment of membrane coughed up on January 19th. Cultures from this showed large numbers of the Bacillus diphtheriæ (Loeffler) and a considerable number of the Streptococcus pyogenes.

Animal Experiments.—Inoculations of two large guinea-pigs caused death in both, with characteristic lesions.

Case X.—Female, aged seven and one-half months.

January 25th, throat congested; temperature, 102° F. January 26th, large membrane on right tonsil; temperature, 102½° F. January 27th, exudate on both tonsils and between uvula and right pillar; temperature, 104½° F. January 28th, croupy; some pulmonary obstruction; râles over chest; temperature, 104½° F.; prostration came on, exudation in nose and lip and over fauces; cyanosis; temperature between 104° and 105° F.; dyspnœa. Death, February 5th.

Autopsy.—Softening, dark-colored membrane in larynx and trachea, extending into smaller bronchi. Moderate broncho-pneumonia in both posterior lower lobes, with general vesicular emphysema. Kidneys congested, with parenchymatous degeneration. Liver congested. Spleen firm.

Bacterial Examination, Morphological.—The pseudo-membrane was crowded in places with masses of cocci penetrating deeply into the underlying tissues. Here and there, but in no part very abundantly to be seen, were bacilli having the form and size of the Bacillus diphtheriæ, either in clusters by themselves or scattered among the cocci.

Cultures.—From the membrane grew on the plates large numbers of colonies of the Bacillus diphtheriæ (Loeffler). Enormous numbers of Streptococcus pyogenes and many of Staphylococcus pyogenes aureus. From kidneys, spleen, and liver were cultivated Streptococcus pyogenes in considerable numbers, and nothing else.

Case XI.—Female, aged ten and one-half months. February 13th, throat congested, with minute exudate on both tonsils; temperature, 102 to 105.2° F. February 14th, A.M., posterior surface of uvula covered with membrane; serous discharge from nose; temperature, 101.8° F. to 103.6° F. P.M.; membrane covers both tonsils and spaces between pillars and uvula. February 15th, croupy; increasing obstruction; albumin sixty per cent. by vol. Died.

Autopsy.—Voluminous membrane in pharynx and over epiglottis, extending down to the lower bronchi; no pneumonia, but moderate congestion of posterior portions of lungs. Kidney, parenchymatous degeneration; spleen enlarged and soft; liver normal.

Bacterial Examination, Morphological.—Large numbers of intermingled short bacilli and cocci in pseudo-membrane and penetrating underlying tissues.

Cultures.—From the membrane there developed on the plates small numbers of colonies, proving on subsequent tube cultures to be the Bacillus diphtheriæ (Loeffler), but their growth was meagre. Enormous numbers of Streptococcus pyogenes developed, and many of Staphylococcus pyogenes aureus. Cultures from kidneys, liver, and spleen were negative; those from the lungs showed a very few colonies of the Staphylococcus pyogenes aureus.

Animal Experiments.—Guinea-pig died on second day with characteristic lesions.

Case XII.—Female, aged nine months. February 18th, throat severely congested; hoarse; temperature, 102° F. February 19th, minute dots on both tonsils; croupy; laryngeal obstruction; increasing temperature, 104 F.; intubation. February 20th, exudation on both tonsils, extreme prostration; temperature, 105° F. February 21st, membrane covering both tonsils and uvula; breathing labored; dulness over both lower lobes; temperature, 104° F. February 22d, death.

Autopsy.—The larynx was covered with a thin, closely adherent pellicle, extending throughout the trachea and into the second branches of the bronchi. Broncho-pneumonia in posterior portions of both lungs. Kidneys show marked parenchymatous degeneration, as does also the liver; spleen large and soft.

Bacterial Examination, Morphological.—Large numbers of cocci, single and in large clusters, in the superficial and deep layers of pseudo-membrane. No bacilli could be found.

Cultures.—From the membrane were cultivated the Bacillus diphtheriæ (Loeffler) in moderate numbers; large numbers of Streptococcus pyogenes and many colonies of Staphylococcus pyogenes aureus, albus, and citreus. The lung cultures showed many streptococci, and a very few staphylococci and Loeffler's bacillus. On the spleen and liver cultures a few colonies of streptococcus grew. The kidney cultures were negative.

Animal Experiments.—Inoculation of medium-sized guinea-pig with sediment of four days old beef-tea culture of the Loeffler bacillus caused death on second day, with characteristic lesions and growth of the specific germ from the seat of injection; no growth from the blood or viscera.

We have thus, in this series of twelve wholly uncomplicated cases of diphtheria, found the Bacillus diphtheriæ (Loeffler) in eleven, and, as is usual, only at the seat of local lesion. A streptococcus having the characters of Streptococcus pyogenes was also present in the pseudo-membrane in eleven of the cases; in the kidney in three; in the liver and spleen in three. The Staphylococcus pyogenes aureus was present in the membranes in eleven of the cases; in the kidneys in one; in the liver and spleen in one. No other bacteria were present with any uniformity or marked abundance in any of the cases.

My own observations are quite in accord with those of Loeffler in regard to the occasional occurrence in both the healthy and diseased pharynx of streptococci, which are in many respects different from the Streptococcus pyogenes. These occasional forms have not been considered in this study, nor the scattering species of other kinds, since they do not seem to come within the scope of the subject in hand.

Nor have I given here the details of technique, since it was in all respects similar to that employed and sufficiently fully described in my former paper.

More and more clearly it appears, as such studies accumulate, that there is one large and important class of cases of pseudo membranous inflammations constantly associated with a particular species of micro-organism, the Bacillus diphtheriæ of Loeffler, which stands in a causative relation to the disease. That a streptococcus often plays a very important, though most likely a secondary, rôle in these cases, seems certain. Equally certain is it in the writer's belief that other classes of cases, often grouped with these and often lacking distinguishing clinical features, are caused by a streptococcus closely similar to, if not identical with, Streptococcus pyogenes, and called the Streptococcus diphtheriæ.

Sufficient evidence has now at last accumulated along the lines of work indicated, so that we are justified, in the writer's opinion, in giving that precision to the problems grouped about the cause, prevention, and treatment of pseudo-membranous inflammations, which has so long been wanting.

We are now, it would seem, justified, as it did not appear to the writer that we were two years ago, owing to the large number of important researches which have been made in the interim, in saying that the name diphtheria, or at least primary diphtheria, should be applied, and exclusively applied, to that acute infectious disease, usually associated with a pseudo-membranous inflammation of the mucous membranes, which is primarily caused by the bacillus called Bacillus diphtheriæ of Loeffler. That this disease is often modified in its course and manifestations by the presence at the seat of local lesion and elsewhere of other pathogenic bacteria, must be assumed as probable. That other forms of acute infectious diseases exist associated with a pseudo-membranous inflammation of the mucous membranes, and caused by wholly different germs, is, as it seems to me, also fully established.

But if the name diphtheria can be universally and exclusively applied to the disease caused by the bacillus of Loeffler, and the latter be regarded as the test of diagnosis, we shall be in a condition to work with definiteness at the various accessory problems, and study more clearly diseases which cluster about and complicate, and not infrequently simulate, the more common and important and fatal disease.

What this class of diseases not caused by or associated with the Loeffler bacillus should be called in distinction from diphtheria, it will perhaps not be possible to say until more extended researches shall have been made upon them, and the specific conditions under which they occur are more definitely known.

It should be clearly held in mind by those eager to draw from experimental studies on the etiology of this disease such practical lessons as shall be of value in treatment, that whether one or more causative agents are at work in setting up those acute infectious diseases which are associated with the formation of a pseudo-membrane, it seems to be fully established that in all of the cases the seat of infection and the origin of the mischief is always a local one. All these experiments point to the paramount importance of efficient local germicidal treatment, and this is equally important whether the bacillus of Loeffler, or the streptococcus, or both together be the infecting agent.

It is the complicating broncho-pneumonia and the systemic poisoning which carry off a large proportion of the victims of pseudo-membranous pharyngitis and laryngitis. That the pneumonia is largely dependent, in many cases, at least, upon the streptococcus, which is so frequently present, seems pretty well established. How much of the systemic affection is due to the streptococcus when this is present in the membrane and in the viscera, as is so often the case, and how much to a poisonous material absorbed from the seat of growth and development of the Loeffler bacillus in the local lesion, it is not possible at present definitely to say. That the poison locally produced by the Loeffler bacillus can and usually does alone cause the characteristic systemic effects in primary diphtheria, is well established.

It seems to the writer that a simple "Liquet" may be uttered on this subject, not as Loeffler [1] believes when such experimental results as seem at the first sight to be out of harmony with his conclusions "shall have been shown to be incorrect," but when they shall be judged on the basis of a definite nomenclature and apart from the thrall of a too limited conception of the nature of those acute infectious diseases which have not a wholly definite characteristic and constant local lesion.

NOTE.—A new and most interesting and important study of eight cases of diphtheria by Welch and Abbott [2] of the Johns Hopkins University, which I regret not to be able to consider in detail has been published since this article was sent to the RECORD. These observers found in all of their cases the Bacillus diphtheriæ of Loeffler. All of their cases were from private practice, and their studies were made from bits of membrane removed during life. Welch and Abbott have determined, contrary to the observation of most of the continental experimenters, that the Bacillus diphtheriæ grows on potato. Their article contains an interesting summary of the later studies on the systemic effects of the poison developed in the growth of this germ, and the conference of immunity by the method of Fraenkel and Behring, to which I can only refer. I am pleased to notice that the critical estimate of Welch and Abbott of my earlier studies, leads them to regard the difference of result obtained from that of most of the continental observers, as due to the peculiar nature of the cases which, as I have indicated in this article, seem to be not primary diphtheria but dependent upon the complicating conditions under which the cases occurred.

NEW YORK, March 10, 1891.

Hospital Graduate Club in Philadelphia.—The ex-resident physicians of the Pennsylvania Hospital have organized an association of which Dr. William Hunt has been elected president. A handsome portrait of Dr. James H. Hutchinson has been presented to the association.

LUPUS OF THE NOSE AND THROAT—DEMONSTRATION OF CASES UNDER THE KOCH METHOD OF TREATMENT.[1]

BY CLARENCE C. RICE, M.D.,

PROFESSOR OF DISEASES OF THE NOSE AND THROAT, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

KOCH has given to the study of lupus a fascination which is hardly surpassed by the present intense interest in the new method of treating pulmonary tuberculosis.

Koch, tuberculosis, and lupus are the three words at present most often heard in the conversation of medical men.

Whatever of curiosity concerning the pathology of lupus had subsided after the experimental investigations of eight years ago, has been more than revived with the advent of the Koch method of treatment. All physicians are so thoroughly acquainted with the results of the recent studies of lupus and tuberculosis, and they have followed the treatment of these diseases with such intelligent interest, that I fear I shall be able to add little to the knowledge of the gentlemen of this Society. We can hope only to place before you the results of the patient researches concerning the pathology of lupus which have been conducted during the past decade, and to add our small mite of experience gained by the good fortune of having the opportunity to study the clinical aspects, and to observe the results, in the treatment of two cases of lupus by the Koch method.

All literature in regard to the pathology, all opinions and theories as to the etiology of lupus, published prior to 1882, are to-day of little value in view of the much more positive knowledge we have of this disease. A new era was begun when Koch [2] in 1882, announced the discovery of the tubercle bacillus, and demonstrated its presence in lupus nodules as well as in diseased pulmonary tissue.

The identity of lupus and tuberculosis was suspected, and the belief that lupus was a localized tubercular process of the skin was held, before Koch's positive knowledge was published to the world.

We may speak of Friedlander [3] as among the foremost to assert that lupus of the skin was a tubercular process. His opinion was based upon the fact that he found lupus nodules to be, microscopically, composed of the same histological formation as tubercular tissue; both resembling granulation tissue and composed of small spheroidal and giant cells. Vidal and Leloir,[4] too, made many microscopical examinations of lupus tissue, and they reported that these nodules were "composed of small cells in the midst of a very delicate network, and each enclosed by a wreath of embryonic elements interspersed with giant cells," and "that these cells are aggregated into primary nodules which again are brought together so as to constitute secondary nodules, exactly like tubercular follicles."

But the controversy as to the relation between lupus and tuberculosis was not, and probably never would have been, satisfactorily settled, so long as investigators argued only from a standpoint of knowledge obtained by microscopical study. Most microscopical appearances which have been considered characteristic and specific of a single pathological condition, have eventually been found to be present in several types of diseased tissue. The giant cell which was thought to be peculiar to tubercular growth, is now found in lupus and hard chancre, and the caudated cell of carcinoma is no longer an infallible guide to diagnosis.

Nevertheless it was a long step in advance when it was demonstrated that, microscopically, lupus and tubercular tissue could not be separated one from the other. Dela-

[4] Vidal and Leloir: Journal of Cutaneous and Venereal Diseases, New York, vol. i., p. 349, 1883.

field and Prudden [1] say, "The morphological character of the lesion long ago led to the conjecture that lupus was in reality a form of tubercular inflammation, and the view has now become established by the numerous observations which show the very constant presence of the tubercle bacillus at the seat of inflammation." Senn [2] puts the matter concisely in the following words: "The advance in our knowledge of the etiology of tuberculosis, the discovery of the bacillus, and the production in animals of tuberculosis by the implantation of lupus tissue, have finally settled the identity of tuberculosis and lupus."

If it were necessary to multiply the evidence showing that lupus and tuberculosis are occasioned by the same pathogenic germ, we could cite the experiments of Schüller,[3] who injected fragments of lupus tissue into the circulation of animals, and invariably produced pulmonary tuberculosis; and of Koch [4] himself, who inoculated the anterior chamber of the eye of eighteen rabbits from tissue derived from five lupus cases, and produced in all tuberculosis of the iris, followed in a number of instances by general tuberculosis. These same experiments were done also by Doutrelepont [5] and others. Koch [6] was able to procure a pure culture of the bacillus of tuberculosis from a lupus nodule, and produced typical tuberculosis in five instances by the inoculation of the fifteenth generation of this culture, one year after the first inoculation.

If we fully accept Koch's conclusions, we must believe that all pathological processes are tubercular wherever the bacillus is found; and most authorities have met on this common ground. Green,[7] in his most simple and clear article on lupus and tuberculosis, says: "The constant presence of an organism in association with a specific type of disease, is very strong evidence of an etiological connection between the germ and the disease."

In addition to the fact that there is this striking similarity of histological structure in the tissues of lupus and tuberculosis, and that the presence of the tubercle bacillus can by painstaking search nearly always be demonstrated in lupus nodules, and again, that artificial tuberculosis can be produced by the inoculation of cultures derived from lupus, there is still another point of evidence corroborating the intimate relationship of these two diseases, viz., that persons suffering from lupus are particularly liable to contract, late in life, pulmonary tuberculosis.

Dr. George H. Fox, of this city, tells me that his observations confirm this fact. This is also substantiated by Demme,[8] who speaks of the prevalence of tubercular affections among the relations of those who suffer from lupus. Rassdnitz,[9] who tabulated 209 cases of lupus, found that one-third of them presented evidences of tuberculosis; and Bessnier [10] found pulmonary tuberculosis in eight cases out of thirty-eight cases of lupus.

Dr. Felix Block [11] gives some valuable statistics. He tabulated 144 cases of lupus and found that 114 of these, seventy-nine per cent., were affected with some form of tubercular disease, either prior to, or following the attack of lupus, and the author therefore concludes that lupus is a chronic tubercular disease of the skin. Among these 144 cases he observed one each of lupus of the pharynx and larynx.

And lastly, and perhaps as strong a proof of the identity of lupus and tuberculosis as any we have mentioned, we can state this evening, as our own experience, that in the undoubted case of primary lupus of the pharynx and larynx which has been presented to this Society, the most marked benefit has been produced by the inoculation of the Koch fluid, suggesting that the disease which we call lupus is a localized tuberculosis, and is influenced by the parataloid of Koch.

It is right to consider for a moment the opinions of those thinkers who have not been convinced by the discovery of the tubercle bacillus. Kaposi contends that the identity of the bacillus of lupus and of tuberculosis is not proven. In a dignified article just written by Jonathan Hutchinson,[1] this careful observer says, speaking of the pathology of lupus vulgaris: "It may be that the process takes its origin as a variety of inflammation and is induced by any one of many local causes of irritation." "This latter theory," he adds, "by no means wholly excludes the influence of the parasite, for it is easily conceivable that a certain condition of local irritation may be the almost necessary precursor of the implantation of the parasite;" and he states this to be his belief rather than that the tubercle bacillus is the sole etiological factor in lupus. He adds, as his clinical experience "that there is nothing less common than to see a patient suffering with lupus pass into phthisis." Microscopical and bacteriological study have, too, cleared away very much the mists which have surrounded our knowledge of the pathology of the scrofulous diathesis. The term scrofula will be but little used in time to come, and we shall not hear frequently of scrofulous inflammation of mucous membranes. Perhaps the term lupus will be discarded from dermatological text books, and Senn's [2] classification, placing lupus under the heading and as one of the types of the several "Clinical Forms of Surgical Tuberculosis," be more generally followed. It is quite probable that we shall speak, not of lupus, but in its stead of a tuberculosis of the face or of the larynx.

Before speaking of lupus of the nose and throat—the title of this paper—it has seemed important to clearly understand the pathology of cutaneous lupus, because we shall expect that lupus of the mucous surfaces will depend upon the same causative factors for its existence. As is perfectly well known, lupus of the mucous membrane of the respiratory tract is very rarely primary, but almost always secondary to lupus elsewhere, most frequently of the face. Garré,[3] writing in 1889 of a case of primary lupus of the pharynx and larynx upon which he performed the operation of pharyngotomy, says that in all German literature there is only one well-authenticated case of primary lupus of the larynx, that of Ziemssen.[4] It will be noted, therefore, that in nearly all the cases the diagnosis of lupus of the nose and throat has been made less difficult by the significant presence of cutaneous ulceration. There are one or two general considerations, in regard to the pathology and etiology of lupus of the nose and throat, to be noticed before we speak of these diseases more in detail, and the following questions seem urged upon us: If lupus is a localized tubercular process, why do we not give to its manifestation in the throat the name of pharyngeal or laryngeal tuberculosis? We might do so at once, were we not hampered by the fact that we are using these very terms to define a pathological condition of the throat which differs in a marked degree from lupus of the throat, as we have observed this disease, both as to physical appearances and clinical history. Which one of these two processes, then, should be called tuberculosis of the throat? or are they both properly designated by this name? And if they are both exhibitions of a tubercular process, why are they so unlike? And being one and the same disease, why are we exhorted to exercise great diagnostic skill that we may differentiate lupus of the throat from

the disease we know so well as tuberculosis laryngis? We should like to be a little clearer on these points, and understand the relationship of these hitherto widely separated diseases, and see if they could not be brought together into the same family. It is my belief that such a reconciliation will be an easy one, and that the widely varying physical appearances and clinical aspects of these two forms of disease are not difficult to explain. I would designate lupus of the throat as a chronic localized tuberculosis, and to the disease we are in the habit of calling "laryngeal tuberculosis," I would give the name acute or subacute general tuberculosis. Fraenkel[1] says "that cutaneous lupus is a tubercular affection of a peculiar character, and in its clinical symptoms but little similar to other tubercular changes, and that it impresses one as a peculiar, unique disease, and it cannot as yet be definitely stated what the causes are for these differences in the clinical attitude of ordinary pulmonary tuberculosis and lupus."

We have always experienced the same difficulty in explaining the difference clinically between a lupus ulceration and a tubercular ulceration of the throat, but, granted that one is a localized deposit and the other a general one; that one is a chronic process and the other an acute one—that one form of disease occurs in comparatively healthy people, and the other in patients dying of pulmonary consumption; is not the different conduct of these two inflammatory processes rationally explained? Let us keep the extremes of these three conditions in our minds. Lupus of the throat attacks a somewhat congested mucous membrane; tuberculosis a pale one; lupus shows strong tendency to the formation of new-growth, and after ulceration has taken place, its endeavor to repair is evidenced by extensive granulation; while a tubercular deposit breaks down before anything like stable tissue can be built up, and there is not sufficient vitality to make much attempt to restore the loss of tissue. Lupus leaves cicatrices, tuberculosis very rarely does so. The ravages of lupus are often deep, because the infiltration is deep and the new-growth extends still deeper, and consequently, when the ulcerative stage is reached, the whole structure gives way. The ulcerations of tuberculosis are superficial, because the deposit is near the surface and has no power to work inward. We must spend no more time here, but it has seemed wiser to us at the outset to endeavor to explain the different behavior, under opposite conditions, of what we believe to be the same inflammatory condition, rather than later on to formulate a fictitious differential diagnosis between lupus and tuberculosis of the throat.

Now, as to the clinical aspects of lupus of the nose and throat. Lupus of the nose is of far less interest to us than lupus of the pharynx and larynx, because, as a rule, it presents few symptoms and gives but little annoyance to the patient. It is almost always secondary to lupus of the cutaneous surface of the nose, and extends to the mucous membrane directly from the skin. I have seen three cases, all of them following ulceration of the skin of the nose. In all the process was very slow, and the damage done was not extensive. In two there was perforation of the septum, and in the third ulceration upon the septum, which probably destroyed it at a later period.

The pathological conditions of lupus of the nose are undoubtedly the same as of lupus of the throat, and I have had an opportunity of watching the different stages of this inflammatory process. First, the stage of infiltration or deposit, marked by slight congestion of the mucous surface, but by considerable thickening and tumefaction; this infiltrated tissue is apt to break down quickly, but the ulcerations are slow to increase in size or depth. The ulcerations are found both on the turbinated and septal sides of the nostrils. The covering of these ulcerations by thick, darkish-brown scabs, as spoken of by Hebra,[2] Kaposi, and others has been marked in the cases I have seen. These scabs become hard, thick, and rigid, and produce sometimes uncomfortable fissure of the nose. The same tendency to a heaping up of pale, friable granulation points, is a distinguishing feature of the pathology of nasal lupus. This stage may be noticed in one portion of the nose, while in another ulcerations bare or covered by scabs may be seen. Patients suffering with this disease will notice blood on their handkerchiefs, but epistaxis is not a common symptom. My patients suffered but little pain; there was an uncomfortable burning, but they referred this rather to the ulceration of the integument. I should say, be suspicious of the presence of lupus of the nasal mucous membrane, whenever a patient suffering from lupus of the skin of the nose is annoyed by nasal obstruction, or notices a bloody discharge. Rhinologists do not have frequent opportunities of studying lupus of the inside of the nose, as these cases go to the dermatologists for treatment. If we would examine all the cases in wards devoted to diseases of the skin, I dare say we might find that lupus of the integument of the nose extended beyond the muco-cutaneous junction more frequently than we now suppose. I have examined five cases of lupus of the outside of the nose during the past week, but in none of them had the disease extended to the mucous surface. Block,[1] whose statistics I have already quoted from, found that in 135 cases of lupus, the process was either primary or extended to the mucous surfaces in 14 instances; in ten of these the nasal mucous membrane was attacked, in two the conjunctiva, and in one each the pharynx and the larynx. Facial erysipelas is not an infrequent complication of lupus of the nasal mucous membrane, just as it is in a fissured condition of the nasal lining from any cause. Dr. Van Santvoord[2] gives the history of a case of lupus occurring in a boy aged fourteen. The disease commenced in the nose. The ravages of the ulceration were extensive, destroying the nose, hard and soft palate, and attacking the larynx; the boy died of meningitis after an illness of five days. I do not think it necessary to give in detail the histories of my three cases of nasal lupus; they all occurred in women. In two, the lupus commenced at the fourteenth and seventeenth year, and in the case presented this evening, at the fourteenth year. The diagnosis of this condition, should it occur primarily upon the nasal mucous membrane, would not be easy. Syphilitic ulcerations are attended by much greater evidence of inflammatory action, the process is much more rapid, the stenosis greater, the discharge muco-purulent. The history of the case, and the benefit or not derived from anti-syphilitic treatment, are points to aid us. The characteristic mounds of granulation tissue point to lupus, and with such an appearance we should naturally search for the tubercle bacillus. The effect produced by the administration of the parataloid will be a strong differential point. The patient presented this evening, suffering from nasal lupus external and internal, has had lupus of the integument of the nose for twenty-two years, and lupus of the nasal mucous membrane so long at least as I have had charge of the case, now two years. I had been unable to materially benefit the condition of the inside of the nose, though I had tried all manner of astringents, caustics, iodoform, etc. She has taken iodid. potas. at various times, and in large quantities. Dr. G. H. Fox, who has also treated her, was unable to heal the ulceration of the integument. Inoculations of the parataloid were commenced January 2, 1891. She has had twelve in all; there has always been a reaction following each inoculation, as shown by redness of the surface of the nose and slight rise in the temperature, once as high as 101⅕° F. The improvement has been rapid and marked. The ulcerations, internal and external, have almost entirely healed, and thus far there seems to be no tendency to recurrence.

Lupus of the throat stands next for our consideration,

and by throat I mean the pharynx and larynx. Lupus in this location is of far greater importance, both pathologically and clinically, than lupus of the nasal mucous membrane. It is a disease of great pathological interest, because it may occur primarily in the throat, or if the throat is attacked after lupus nodules have appeared on the skin, it is an independent deposit, and not, as in the nose, a simple extension of the ulcerating disease. It is of great pathological interest, because of the great difficulty in recognizing it and in separating it from syphilis, tuberculosis, and malignant disease. Clinically, lupus of the throat is of greater importance, perhaps, than lupus upon any other portion of the body; because, although slow and insidious in its behavior, it destroys most important parts. It needs to be studied carefully. Although a rare disease, we shall find quite enough literature concerning it; and it will be no easy task to separate the chaff from the wheat. We shall be helped only by those writers who state carefully the points upon which their diagnoses have been made, and who give an intelligent and faithful picture of the appearance of this variety of ulceration.

Chiari and Ruhl[1] did a great service when, in 1882, they collected all the cases of lupus of the larynx which had been published up to that date. They tabulated but 30, the first 4 having been observed by Türck,[2] and published in 1866. This publication stimulated Holm,[3] of Copenhagen, to examine the larynges of all patients suffering from cutaneous lupus. His observations extended from 1866 to 1877, and he saw 6 cases of laryngeal and pharyngeal lupus out of a total number of 106. At the skin clinic of Vienna it was found that eight per cent. of all lupus patients had ulcerations upon the throat—6 out of 68 cases. Hashund,[4] writing in 1883, had tabulated his cases from 1866, and had seen, up to 1882, 215, among which number he had found 15 cases of laryngeal lupus, about seven per cent. Lennox Browne[5] observed 3 laryngeal and 3 pharyngeal cases among 25 of lupus, about twenty per cent. If from these figures we strike an average, we shall find that about twelve per cent. of all cases of cutaneous lupus have secondary deposits in the throat. And Hunt,[6] of Liverpool, says if we add to this number those cases involving only the mucous membrane of the upper air-passages the average will be brought up to nearly twenty per cent., or one-fifth of all cases. We believe this average to be too high; nevertheless, it is probably true that many cases of lupus of the integument have lupus of the throat, and this latter lesion passes unnoticed. Ziemssen[7] remarks that many cases of cutaneous lupus had hoarseness and laryngeal cough.

Browne, of London, saw more cases of lupus of the throat in a single visit at a skin hospital than he had seen in twenty years of private practice. With the advent of the Koch method of inoculation for the treatment of lupus, we shall undoubtedly hear of a much larger number of cases in the future than we have in the past.

I had no idea of reviewing the literature of lupus laryngis until I saw the patient I have presented this evening; and in describing the pathological conditions of this disease I shall be obliged to make use of this case for my text. This is the only case of undoubted lupus of the larynx I have seen. I believe I have examined one more case, though I did not recognize it as such at the time. I often wonder, were we to be carried back to "Old Charity," if we could not find among its prolific pathology almost any rare disease we wished. Reference to the books of those days would, alas, be of little use, so many of the histories were written, the acquaintance of the patient never having been made; but I remember having seen peculiar cases of ulceration of the throat. The leprosy cases were there then. But I digress. Enough has been said concerning the etiology of lupus of the throat, except to add that the average age of Chiari's tabulated cases was twenty-one years, which tallies very closely with figures given by other writers. There were sixteen females and seven males, the sex of seven not given.

If we are agreed to put down the tubercle bacillus as the exciting cause, we can mention only traumatism and the tubercular diathesis as the predisposing causes. As to the pathology, when I first examined my case the

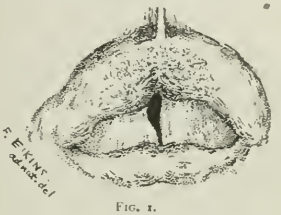

Fig. 1.

appearance of the epiglottis impressed me most. It was different from any epiglottis I had ever seen—thickened, infiltrated, of a higher color than the turban-shaped epiglottis of phthisis, and less red than an epiglottis acutely inflamed by a syphilitic ulcer. The surface was granular, almost nodular at places, the small projecting points looking very soft and friable, as though they could be rubbed up like bread-crumbs between the fingers. The entire thickness of the epiglottis appeared as if composed of this soft tissue. The destruction of the epiglottis down to the glosso-epiglottic ligament, with the fissure in its centre, could hardly be due to the usual tubercular ulceration. Healing after such destruction we have not seen in laryngeal tuberculosis occurring with pulmonary consumption, and there was none of the hard, brawny induration of syphilis with its deforming cicatrices. The sides of the cut-off epiglottis were adherent to the lateral walls of the pharynx, but this seat of adhesive inflammation presented none of the rigid, unyielding coalescence we are familiar with in syphilis, and was in itself a strong differential diagnostic point against a tubercular process. Perhaps three-fourths of the calibre of the glottis was closed by the same kind of granular infiltration about the arytenoids and the sides of the larynx. The figure (Fig. 1) of the larynx which I should like to present to the

Fig. 2.

Society, and which was drawn from an examination made some two weeks ago, shows the condition very well, and it will be noticed that the laryngeal opening is considerably larger to-night than it was at that time. The arytenoids were but slightly movable, and one presented a convex surface to the concave surface of its fellow, an unusual kind of infiltration; the vocal bands were hidden beneath the overhanging sides of the larynx, which seemed built up in a true perpendicular line. The dyspnœa was much less than we should have expected from the amount of occlusion, and there was no dysphagia. The voice was a husky whisper. The ulcerations about the pharynx were next noted, and they have changed

considerably since the first inoculation of the parataloid (Fig. 2). The ulcerated surface presented the same friable appearance as did the epiglottis, except that the small shining tubercles were more elevated than upon the epiglottis; the ulceration was superficial as in tuberculosis, but was not covered by the grayish muco-pus seen in that disease, while the surrounding tissues were of a much more healthy color. There was, however, too much of the worm-eaten appearance about the ulcerations to remind one of the ulcerations of syphilis. The posterior pillar on the right side was matted down and inseparable from the posterior wall of the pharynx, but it did not, as in syphilis, look as though one surface had become adherent to the other, but rather as though the two surfaces had grown into each other by a process of slow infiltration and sluggish ulceration. There was ulcerated surface on the middle wall of the pharynx, but it healed after the first few lymph injections, and has left but little cicatrization.

The only points in the history of my case, of any value to my paper, are the following: Miss W——, aged twenty, native of New England, seems to be in good health but not robust. Father died of apoplexy, mother living, and in good health. She has one brother who was said to be scrofulous, and threatened with consumption. Patient has never had serious illness. She lost her voice four years ago, whereas the nodule on the side of the nose appeared last spring, so that the primary seat of the disease is the throat. There has never been pain about the throat. The patient was very kindly referred to me by Dr. A. M. Phelps. Dr. G. H. Fox pronounced the nodule on the side of the nose to be one of lupus; and I have received the following microscopical report of specimens taken from the ulceration of the nose:

"I have examined some of the discharge from the lesion on the side of Miss W——'s nose, microscopically. Cover-glasses were pressed directly against the sore, and afterward treated with Ziehl's carbol fuchsin stain for tubercle bacilli. Careful investigation revealed the presence of a few tubercle bacilli in the preparations.

"JOHN H. LINSLEY,
"*Laboratory, Post-Graduate School.*"

This patient has received thus far eleven injections of the parataloid. The first three were one half a milligramme each—the largest dose administered was three milligrammes. The reaction was very irregular, the highest temperature following an inoculation being 101⅕° F. There have been no symptoms of discomfort following the administration of the parataloid. The effect of this treatment has been to reduce in a remarkable way the amount of infiltration of the larynx. The arytenoids have been relieved of much of the load of superimposed granulation tissue, and now move much more freely. After the first few inoculations the swellings on the sides of the larynx had disappeared so much that the vocal bands could be seen, and it was found that they were intact. The patient's voice is almost normal and the breathing easier. In this case I have witnessed more than in any other the beneficial effects of the Koch fluid.

How do the pathological appearances presented by this case compare with those observed by other writers? Türck [1] says that there were ulcerations and loss of tissue upon the epiglottis in all his cases, and in describing the granulations so typical of this disease he says they are "wart-like when large, but produce simply unevenness of surface when small." Türck depends mostly upon the accompanying skin lesion for diagnosis, but this was in 1866.

Lefferts,[2] of New York, who published an interesting case of lupus of the throat in 1878, says the essential pathological element is hypertrophy of tissue, hyperplasia, and infiltration, followed by ulceration. The epiglottis in his case was much hypertrophied and covered by minute fleshy granulations. He places emphasis on the "worm eaten" ulcerations and the granular epiglottis. In his case, like mine, the larynx was blended into one mass of homogeneous tissue. Unlike Lennox Browne's pathology, we have not in our case the hard and unyielding cicatrization following ulceration.

Hunt,[1] of Liverpool, who seems to have seen a number of cases, emphasizes what he calls the anæsthesia of the larynx, and we have mentioned this symptom in our patient—entire absence of pain, in spite of the thickening and ulceration. Gottstein, Orwin, and others mention this, and say that the symptoms are slight and not at all in proportion to the physical appearances. Absence of pain, however, is not a constant symptom, for there was dysphagia in the cases observed by Lefferts and Asche. Browne speaks, too, of the solid infiltration of the uvula, a condition well marked in my case. A strong differential point mentioned by a number of authorities, and strikingly illustrated by my case, is the limitation of the disease to the supra-glottic region, the disease extending only to the vocal bands. For this reason the voice returns very rapidly when the infiltrated tissue above the vocal bands becomes absorbed. I find, however, some exceptions to this rule, for in a few cases there has been destruction of the vocal bands. Hunt, whom I have quoted before, says: "In time all the structures of the larynx may be involved."

Eppinger [2] speaks of the "dry base of the ulcers in lupus," and in Ganghofner's [3] case there was the same adhesion between the epiglottis and the lateral walls of the pharynx which was observed in mine.

Adhesion between the anterior ends of the vocal bands, noted in two of the recorded cases of laryngeal lupus, I have seen in tuberculosis of the larynx, but it is a much more characteristic lesion of syphilitic ulcerations.

I have no comment to make upon the statement that the involvement of bone is a conclusive test between syphilis and lupus. Lupus certainly attacks bone very rarely. Hunt, however, states that there was necrosis of the nasal bones in one of his cases. I am pleased to find that Browne mentions the appearance which was so noticeable in my case, that the stenosis of the larynx was due to a "matting together of the tissues."

Auspitz [4] claims a singular pathological condition for lupus occurring on mucous membrane: that "destruction may take place from simple atrophy, and that scars may be left without ulceration."

But I must hasten to a close. The differential diagnosis between lupus, tuberculosis, and syphilis of the throat has always been a subject of much controversy, but the writer of to-day can mention two factors which go far toward solving the difficulty, and which will not be found in literature of any age: first, the diagnostic value of the presence of the tubercle bacillus, and second, the effect on the disease of the Koch treatment. This latter will go hand in hand with anti-syphilitic treatment as a diagnostic point. In the larynx we believe it to be more difficult to diagnose lupus from tuberculosis than from syphilis. But this will depend upon which stage of the disease is studied. In the early part of the disease, the infiltration of lupus, the granular appearance of the mucous membrane, the color, and even the superficial ulcerations, are much more like tuberculosis than like syphilis, Lupus is much slower in its progress than tuberculosis; it very rarely attacks the vocal bands until late in its course, while tubercular ulcerations show a marked preference for the true cords. If, however, the larynx is left deformed by deep ulceration and thick rigid bands of scar tissue (and I have not seen this condition), then we can understand that it may be exceedingly difficult to exclude the ravages of syphilis. We shall, however, be called

[1] Türck: loc. cit.
[2] Lefferts: American Journal of the Medical Sciences, April, 1878.

[1] Hunt: loc. cit.
[2] Eppinger: Klebs Handbuch der Path. Anat., 7 Heft., p. 162

[4] Auspitz: System des Handbuch. Wien, 1881.

upon to diagnose few lupus ulcerations of the throat which are unaccompanied by lupus of the skin.

It is our opinion that the use of the parataloid, which seems to have a more marked effect upon lupus than upon any other disease, will be of positive service in excluding syphilis from lupus of the throat; whether it will aid us in separating lupus from tuberculosis we must wait longer to ascertain. My experience thus far indicates that a much greater reaction is obtained in lupus than in tuberculosis, probably for the reasons stated early in this paper, that one is a local and the other a general infiltration, and that the condition of the patient is much better in one than in the other disease.

In passing, I cannot refrain from alluding to the totally different effect of the Koch fluid in my case of lupus of the larynx from the results of similar treatment in cases recorded in Europe. In a number of instances, as we read, the occlusion of the larynx, which was considerable before the treatment was commenced, was so much increased after the first two inoculations that tracheotomy was performed. In my case, although the congestion of the mucous membrane was obviously heightened, there was a rapid and uniform decrease of the infiltration and a corresponding improvement in breathing and voice. Tracheotomy was performed twice under such conditions by Professor Gerhardt, and we read of another such operation in a case treated by Dr. J. Michael,[1] of Hamburg.

Turck [2] speaks of the difficulty, and sometimes the impossibility, of differentiating lupus of the larynx from leprosy of the larynx. I do not share his opinion. I saw three cases of leprosy of the larynx at Charity Hospital, in 1878. They were in the service of the late Dr. Louis Elsberg, and were published in the MEDICAL RECORD.[3] In all three the pathological condition was very much alike—large, hard, warty nodules over the epiglottis and sides of the larynx, much larger and coarser than in lupus. I should say that it was as easy to differentiate these two diseases when occurring in the throat as when seen upon the skin.

I have not thought it of value to this paper to cite the little peculiarities of the many individual cases of lupus of the throat which may be found in the current literature, nor to allude to the discussion which followed the presentation of the cases of lupus of the throat before the American Laryngological Association [4] by Drs. Knight, of Boston, and Asche, of New York. During the study of this literature I have been impressed with the fact that Americans are good observers, and can clearly state clinical appearances.

In conclusion, let me repeat the following points, which I hope I have made apparent in my paper:

1. That the discovery of the tubercle bacillus in lupus nodules and the demonstration that artificial tuberculosis can be produced by the injection of a bacillar culture obtained from lupus tissue are strong proofs of the identity of lupus vulgaris and tuberculosis.

2. That lupus of mucous membranes is of the same histological formation as cutaneous lupus. And as the tubercle bacilli have been found in lupus of the throat this disease probably bears the same relation to general tuberculosis as does lupus of the integument.

3. That we believe lupus of the throat to be a chronic localized tubercular process, while ordinary tuberculosis of the larynx is an acute or subacute general tubercular process.

4. That lupus upon mucous membranes occurs in about twelve per cent., or one-eighth, of all cases of lupus vulgaris.

5. That the diagnosis of laryngeal lupus is not difficult, because it usually is accompanied by lupus of the skin.

6. That in primary lupus of the larynx the two most important factors in diagnosis are the discovery of the tubercle bacillus and the effect of the injections of parataloid on the disease.

7. That while marked benefit has been derived in the case of lupus laryngis, which forms the basis of this paper, we must wait longer before deciding whether the large hopes which have been entertained by the medical profession, of curing lupus and tuberculosis by the Koch method of treatment, are to be realized.

A CASE OF HYSTERICAL AORTA.

BY SARAH E. POST, M.D.,
NEW YORK.

THE patient was a woman of about thirty-five years of age, the mother of two children, the youngest six years of age—no intervening miscarriage. The last menstruation was about December 25, 1890. About the first of February, or following the first missed period, the patient was seized with vomiting, accompanied by great prostration. She went directly to bed. She was profoundly depressed even at this time. I should have mentioned, perhaps, that while she was apparently well nourished the patient had already evinced some lack of vascular control. She had a flush over the check-bones which almost amounted to an appearance of hectic. She had had, too, a noticeable swelling of the thyroid in the fall of 1890, which had subsided after a month's treatment. The patient continued vomiting, but she supposed herself suffering simply from the vomiting of pregnancy, and a doctor was not immediately called in. In the latter part of February there commenced an almost constant spitting of mucus and blood. The gastric intolerance continued. The local medical man was now summoned, and physical examination revealed, in addition, an easily defined epigastric tumor. A consultation was requested, and two other physicians were called in. One of these was a Bellevue Hospital man. I could add that the other two consultants were also men of liberal education and hospital experience. I simply mention this fact to show the deceptive character of the case. Three well-educated medical men pronounced this a case of gastric cancer. The evidence was gastric intolerance, spitting of mucus and blood, profound depression, suppressed menstruation, cachexia, and a tumor in the epigastrium. I neglect to say that this tumor was distinctly lifted with each pulsation of the aorta. Stethoscopic examination, however, failed to reveal any evidence of aneurism, and the pulsation was supposed to be due to the fact that the aorta was overlaid by the mass. The patient, then, had cancer of the stomach. Operative measures were out of the question, her depression was so great. The family were made acquainted with the decision, and an over-conscientious husband told the patient. It was at this stage, and after the complete withdrawal of hope, that I first saw her. The patient was being cared for by her home people, and I was sent for in the hope that my knowledge of nursing would enable me to suggest ways of making her more comfortable. The doctor consented to meet me, with this object in view. There was at that time no doubt in regard to the diagnosis in anybody's mind, no doubt in my own mind. The writer of this sketch had, however, *lived with* three patients who had died of cancer. She knew the physiognomy of the disease. Coming into the room she saw a desperately sick woman, but not a woman prostrated to that degree with cancer. She didn't look like cancer. That matter being settled, it became comparatively easy to hunt about for some other explanation of her condition. The tumor, of course, was a most important matter; but here, too, fortune favored her. The tumor, which rose up well into the field of examination, could be followed from the ensiform cartilage to the umbilicus, and from there still followed for about an inch to the left. It was cylindrical, it pulsated. I say fortune favored me at that first examination. Subsequently I examined the tumor when it was limited

to the epigastrium, and was apparently a rounded mass. Again I have found it only at the umbilicus.

I next, with the history of suppressed menstruation, examined by vagina, and found an enlarged, retroflexed uterus. Without more exact tests I ventured on the following diagnosis: 1. Pregnancy in a retroflexed uterus, with shock complicating the nausea and vomiting of this condition. 2. Shock and lack of nourishment producing loss of vascular tone, resulting in what may be called hysterical aorta. This condition I had heard described by the late Dr. E. D. Hudson, and I had once seen it at my clinic at the Demilt Dispensary, the diagnosis being sustained by the disappearance of the tumor under iron. I had never seen it as a complication of pregnancy. Dr. Anna Lukens has seen it once in an eight years' experience as resident physician at the Staten Island Branch of the Nursery and Child's Hospital.

The patient had now and then epistaxis, she had a pharyngitis, and her tongue was dry and cracked. It seemed easy to account in this way for her spitting of mucus and blood; but I quite failed to appreciate the gravity of this symptom. Improvement of the nutrition seemed to me peremptorily indicated; but my suggestions were limited to matters of food; they did not include iron. I did not realize that we had to deal with a profound cachexia, as pernicious in its special way as that of carcinoma in its. I instituted rectal alimentation with success. The retroflexed uterus was elevated, vomiting was controlled, so that a twenty-four hours' interval would be afforded, and the patient commenced to crave food, but without much gain in strength. The tumor disappeared, but the stomatitis and pharyngitis totally resisted control; the tongue ulcerated where it rested upon the teeth; the patient announced that she was unable to swallow; diarrhœa prevented further nourishment by enema; the pulse rose in frequency, and the patient died, after about four weeks of supporting treatment, consciousness being preserved until an hour from the last.

Autopsy showed no gross disease of the abdominal organs. The uterus was enlarged to a two months' pregnancy and showed the adherent chorion of a blighted ovum. The throat was not examined, but there was at no time any ground for supposing that the mouth and throat trouble was diphtheritic.

I am sorry not to be able to report the recovery of a case of simulated carcinoma ventriculi, but the teachings of the case seem to be clear. It is a mistake to allow the essential diagnosis to blind one to what are apparently minor symptoms. It is doubtful whether in this case iron could have been borne. It was, however, in the light of the *aenouement*, undoubtedly indicated; and that not in tonic doses, but in doses as heroic as those with which we fight erysipelas or diphtheria.

As to the pathology of hysterical aorta; it is shrouded in mystery. When examined by autopsy the aorta in this case had the ordinary calibre. I have noted the fact, however, that with the improved alimentation the tumor had disappeared a week before death. This patient had the hot hands and feet found with diminished vascular tone. She would uncover her feet in order to cool them, yet she at no time had a pyretic temperature; she at no time had sweats or chills. The urine is said to have been negative. In the light of the autopsy acute anæmia was the only factor which warranted a certificate of death. We can only surmise that in these cases a relaxation occurs in the walls of the aorta similar to that which is found in the skin and subcutaneous tissues in grave conditions. I am aware that this assumption suggests many interesting speculations, but it is the only one which I have to offer.

To Abort a Boil.—The ointment of the nitrate of mercury is said to be an excellent application in the case of a commencing boil or felon, its early use in most cases sufficing to prevent the formation of the furuncle.

Clinical Department.

A CASE OF PERSISTING HEMORRHAGE FROM THE CONJUNCTIVA OF A NEW-BORN INFANT, FOLLOWING THE INSTILLATION OF A SOLUTION OF NITRATE OF SILVER.

By G. E. DE SCHWEINITZ, M.D.,

OPHTHALMIC SURGEON TO THE PHILADELPHIA HOSPITAL.

It is well known that Credé's method of instilling a drop of a two per cent. solution of nitrate of silver into the conjunctival cul-de sac of the new born infant to prevent purulent conjunctivitis, sometimes is followed by hyperæmia and secretion of the conjunctiva, which usually disappears in a day or two. Very few instances are on record in which the reaction has assumed a dangerous type, and the enormous value of this prophylaxis of ophthalmia neonatorum has shown that its author's judgment of the strength of the silver solution was wise. A few cases are known in which hemorrhage from the conjunctiva has followed this treatment, and has been attributed to the action of nitrate of silver. A notable example of this kind was published by Dr. Pomeroy in the Medical Record for August 20, 1887. In his case the instillation of a single drop of a two per cent. solution of nitrate of silver, carefully done and without laceration of the conjunctiva, was followed by violent pain, some serous discharge which rapidly became tinged with blood, and gradually developed into "a slow, but persisting, oozing of blood, startling to observe." After treatment, consisting mainly of iced compresses and firm bandages, the hemorrhage stopped, but not before the condition of the infant was most alarming, and the hemorrhage so decided as to prove well-nigh fatal.

The following case occurred in the maternity wards of the Philadelphia Hospital: A healthy colored woman was delivered, at 7 A.M., of a female child. The birth was a rapid one, the delivery of the head and the rupture of the membranes being almost simultaneous. The liquor amnii was of a dirty-yellow color and thick consistency. A drop of a two per cent. solution of nitrate of silver was instilled after the manner of Credé. Three hours later there was redness of the eyes and some discharge. The resident physician then made a second instillation of two drops of a nitrate of silver solution, twenty grains to the ounce. This was carefully done, and there was no laceration of the conjunctiva. The eyes immediately were irrigated with a saturated solution of boric acid, a treatment which afterward was continued each hour. At eleven o'clock at night no purulent discharge was manifest, but a bloody serum began to exude between the lids. The next morning iced compresses and a lotion of alum, four grains to the ounce, were used. In the afternoon I saw the case, and found a fairly well nourished infant with persistent bleeding from the tarsal conjunctiva of both eyelids, the blood leaking out between the palpebral fissures, some of it apparently having found its way through the lachrymal canals into the pharynx, as the child vomited some blood-stained material. The alum collyrium was continued, but no bandages were applied. The next day the hemorrhage continued, and with considerable severity. The eyelids were puffed up and their under surfaces covered with a very tenacious clot. This was removed with forceps, and the hemorrhage seen to occur from numerous points in the form of a persistent oozing. The blood clotted readily. At the end of the third day the hemorrhage stopped, and the bloody discharge was replaced by a slight purulent secretion. A small linear ulcer formed near the edge of the cornea, which rapidly healed under the use of eserine. The child was somewhat shocked by the loss of blood, and the bodily temperature was maintained by the application of external heat.

The mother of this child was perfectly healthy, and never had experienced excessive bleeding herself. She knew of no member of her family who had been so af-

flicted It was not possible to interview the husband, but the wife stated that he had not been a "bleeder," nor, so far as she was aware, had there been any hæmophilic tendency in his family.[1] Examination of the blood-clot did not reveal any unusual composition. There was no scar in the conjunctiva, after it healed, to indicate that any injury had been done to its surface.

While it is not possible to prove that this child bled so persistently from the conjunctiva because of two drops of the silver solution, first of two and then of four per cent. strength, it is none the less true that the hemorrhage followed such applications, and, moreover, occurred not in association with the development of an ophthalmia neonatorum, as the original discharge, which appeared only three hours after instillation, seems more likely to have been of that character which has been noted in several instances as the result of the reaction produced by the nitrate of silver.

I am indebted to Dr. Frances C. Van Gasken for her intelligent care of this case, and to my colleague, Dr. Montgomery, for the privilege of having seen it.

SOME QUESTIONS ABOUT ISSUES AND SETONS.

By CYRUS EDSON, M.D.,

NEW YORK.

Twenty years ago practitioners of medicine held that the issue and the seton were curative procedures of great value. The writer well remembers having heard the virtues of these vaunted by old physicians (and old women). They were thought in some way to drain the system of its impurities—to afford a channel by which materies morbi could effect an egress or be drawn off.

While their use is an ancient one and based upon empiricism abundant evidence exists of their worth. Though we find favorable mention of them in medical works of to-day, nevertheless they are practically obsolete methods of cure, and owe their disuse to the refinement of modern medicine rather than to any lack of therapeutic power.

Now the question occurs, Does the discovery of the function of the phagocytes throw any light upon the action of the issue and the seton?

Metchnikoff has proved that the phagocytes are destroyers of noxious bacilli.

Do not the issue and the seton favor the production of the phagocytes by inducing suppuration?

Suppurative processes in some way increase the number of phagocytes in the blood.

May not ulcerative processes generally be efforts on the part of nature to effect the production of the phagocytes for curative purposes?

There has always been a deeply rooted prejudice against healing any chronic sore, and this feeling has been caused by the frequent occurrence of sickness after it has been done.

I have seen excellent results follow the use of the issue and the seton in several cases, two of which I will give.

Mrs. W——, about forty-seven years of age, a member of the writer's family, was subject for six years to severe attacks of facial erysipelas.

These occurred at intervals of six or eight months. An issue was ordered in accordance with old-time notions as a prophylactic measure, and was established in her arm by means of potassa fusa and an issue bead of orris root.

She never had another attack of erysipelas, remaining in perfect health for nearly twenty years, when she died of apoplexy.

Mr. G——, aged forty nine, was afflicted with recurrent attacks of ophthalmia.

The insertion of a seton in his neck was followed by immunity from the attacks, and I am informed by great improvement in his general health, which has continued for over ten years and to the present time. The seton has been kept running during the entire period and does not, he says, much inconvenience him.

The issue and the seton have been recommended by eminent surgeons, notably Ericksen and Gross, for beneficial effects in cases of joint disease before suppuration occurs.

Their action in these cases, as in those I have mentioned, seems to be something more than that of mere counter-irritants, and I believe that Metchnikoff's discovery enables us to account for it.

Have we done well to discard the use of the issue and seton?

[1] So far as the writer is aware no cases of hæmophilia have been described in the colored race.

URINALYSIS FOR SUGAR QUALITATIVE AND QUANTITATIVE.

By D. W. HOUSTON, M.D.,

TROY, N.Y.

Before prescribing for a patient complaining of loss of flesh, debility, thirst, and increase in micturition, an examination of the urine of the patient is the first important duty of the physician.

There is a method of chemical examination of the urine which gives approximately the percentage of sugar and fulfils all the requirements of a reliable test, which is, I believe, not as generally known as it should be. I refer to the liquor potassæ test, performed in the following manner:

To a quantity of urine in a test-tube one half of its volume of liquor potassæ is added. Then by heating the upper zone of this combination over the flame of a spirit lamp if sugar be present a change in color will be soon shown. The color first appearing will be canary yellow and will indicate, according to its intensity, one per cent. of sugar or less. After further heating the canary color will be displaced by an amber color and this will indicate two per cent. of sugar. The further addition of heat (if there be sugar enough present) produces a dark Jamaica rum color and this will show five per cent. of sugar; and should, after continuous boiling, the color become dark brown and the contents of the test-tube not transparent, then ten per cent. of sugar in indicated. Between the four standards of color here given there may be different gradations showing a greater or less percentage of sugar.

When once sugar is detected in the urine of a patient and treatment begun, the convenience of having a reference for comparison with the first or any subsequent testing is highly desirable, in order to determine the progress of the disease and the results of treatment.

The simplicity, beauty, reliability, and accuracy commend this test as the best for the qualitative and quantitative (approximative) examination of sugar in the urine.

The late Professor Ultzmann, of Vienna, depended almost entirely upon this test in his examinations for sugar, at the Poliklinik.

The Laughing Plant is the name of a plant growing in Arabia, and is so called by reason of the effect produced upon those who eat its seeds. The plant is of moderate size, with bright yellow flowers and soft, velvety seed-pods, each of which contains two or three seeds resembling small black beans. The natives of the district where the plant grows dry these seeds and reduce them to powder. A small dose of this powder has similar effects to those arising from the inhalation of laughing gas. It causes the most sober person to dance, shout, and laugh with the boisterous excitement of a madman, and to rush about cutting the most ridiculous capers for about an hour. At the expiration of this time exhaustion sets in, and the excited person falls asleep, to awake after several hours with no recollection of his antics.—*Medical Times.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 18, 1891.

TRAUMATIC NEUROPATHIES.

IF anything will stay the hand of the ubiquitous surgeon it must be some startling statement of facts to impress upon his mind the relative degree of heat in the frying-pan and the fire. As a rule the frying-pan is no hotter than the fire, and the ills we have may be more endurable than evils unknown and unimagined. Surgery, like other good things in and out of medicine, has definite drawbacks It is not an unmitigated good, for insignificant operations have been followed at times by disaster infinitely more deplorable than the original abnormity. Circumscribed injuries, even the delicate ones brought about by the surgeon's knife, may result in nervous complications of serious import. To cut or not to cut, is a graver question than has been supposed. While works on surgery, naturally the outcome of surgical minds, consider syncope, nervous delirium, and neuralgia the only neurotic complications that may arise from the use of the knife or the presence of wounds, these otherwise valuable books leave something to be desired. There is a surgical side to modern hysteria which it is well to take into account, if painful surprises for the surgeon and his patient are to be avoided.

The effect of slight accidents and disintegrating emotion in the production of neuropathics is considered in *Médecine Moderne*, February 12, 1891, by Dr. Casten, who gives several illustrations of sequelæ of magnitude following slight causes. Herbert Page, Erichsen, Weir Mitchell, Leudet, Lyden, Trossier, Lombroso, Charcot, and Paul Berbez have cited numerous clinical examples of a similar nature, and given to hystero-traumatism a definite place in literature. Less well understood and appreciated are the nervous complications of contused wounds, sprains, and the legitimate lesions of surgical origin that interfere with ordinary occupations but a week or two, and are, therefore, never thought of again except as trivial facts of the past. A woman, thirty-three years old, was knocked down by a milk wagon and dragged some twenty feet, receiving a slight contused wound about the left knee, and some bruises in the region of the left scapula and lower portion of the abdomen. There was no serious injury of any kind, yet within forty-eight hours epileptiform seizures set in at the rate of two a day for about a fortnight. At the expiration of two weeks all manifestations requiring surgical care had disappeared. Ten weeks the patient remained in bed, subject to epileptiform attacks that increased in violence as they lessened in number, rotation of the arms and legs inward, and flexion of the joints of the upper extremities becoming their marked characteristics. A history of earlier causeless mental depression and senseless fits of anger was elicited. Areas of circumscribed anæsthesia were found. Another case of the same order. A girl, of seventeen, was knocked down from behind, and run over lightly by a carriage she failed to see. Picked up in a generally confused and shaken-up condition, her only discoverable injuries were various ecchymoses about the thigh and across the abdomen. Two hours after the accident distinct mental excitement made its appearance, clonic spasm of the limbs followed, incontinence of urine and fæces, and loss of sensation in the right leg. A deep sleep, a sort of coma, set in and lasted for a week. From this somnolence the patient was roused four or five times daily by epileptiform convulsions. There were permanent multiple contractures, general anæsthesia, retention of urine, and loss of the power of deglutition, food being violently ejected. An aura expressed itself as a sensation of cold in the left arm. The tongue was bitten, the thumb drawn between the index and the middle finger, and there was complete unconsciousness during these attacks. Symptoms began to abate in about ten days. The patient then talked a little and could put the feet out of bed. A month passed before she could sit up in bed, prevented earlier by persistent pain in the lumbar region. Retention of urine and general anæsthesia kept up for weeks. After the girl had returned to ordinary health and the duties of life there was sudden spontaneous return of vesical paralysis and weakness in the lower limbs. This was doubtless a case of latent hysteria.

Other illustrative examples are given. In one instance a sprain of the wrist resulted in suppression of menstruation, which was active at the time, and in hysterical manifestations lasting a week. In another instance palpitation of the heart and nocturnal distention of the abdomen appeared as the result of a fall. A little girl, of five, hit her forehead while at play, the spot bleeding slightly. From this untowardness were evolved insomnia, nightmare, anorexia, and general nervousness. Another woman escaped being run over, neither horse nor carriage touching her. Fainting fits, attacks of fear and of tremor dated from this incident.

The author cited looks upon these conditions as forms of hystero-epilepsy. Tissot considers fear the most important cause of epilepsy. Many persons, hitherto exempt, fell victims to this disease during the dark days of the late Franco-Prussian War. The earthquake at Nice so shattered the nerves of many French visitors there at the time that any unusual strain later in their customary Parisian life served to render them speedily insane. Fear, accident, and injury, together or separately, are destructive elements that ought to be more recognized and appreciated as factors in disease. Usually in cases like the foregoing, hysterical stigmata will be present, as constriction of the visual field, hemianæsthesia, hysterogenic areas, and loss of pharyngeal reflex. Prognosis should always be guarded. Though classed as ephemeral, the troublesome nervous symptoms may persist or return. Epilepsy, vertigo, chorea, hypochondria, loss

of memory, general paralysis, and mental alienation resulting from destructive emotion or sudden injury may be permanent. Especially reserved should be medical opinion where circumscribed paralysis is followed by muscular atrophies that are not clearly defined.

It has been claimed that a neuropathic constitution underlies all conditions of results disproportionate to causes. Perhaps so, perhaps not. Such predisposition is often imperceptible before the advent of trauma. It is in each instance a medico-legal question of importance, for temperament should decide affirmatively or negatively a verdict of damages in any given case.

The treatment of neuropathies induced by trauma consists, primarly, in psychic aid, best given by the physician who can explain to the patient with more exactness than any other how utterly without reason for existing are his symptoms, in themselves mere unblessed memories of former jarrings. A literal change of environment is essential, together with rational therapeusis in the form of the bromides, the douche as given in France, and massage of the injured or affected parts. Prompt and vigorous measures are necessary, for abnormal neurotic habits are sometimes most difficult to overcome, and are always wide-reaching in their disastrous influence.

THE NAMES OF THE GRIP.

There is more in a name than Juliet would have us believe, and in medicine especially, we can often learn much concerning the nature and symptoms of diseases that have raged in epidemic form in past ages merely from the names that have been applied to them at different times, and by different peoples. A good example of this is furnished by the strange malady that has been travelling around the globe for the past eighteen months, and which we now call the influenza or grip. The word influenza is Italian, and means nothing more than influence. We find the term first employed in the writings of Huxham, who, in referring to the epidemic of 1743, speaks of a fever "quæ per totam Europam hoc vere sub nomine influenza grassata est." We see from this word how widespread was the affection, since of all epidemic diseases this especially was attributed to an atmospheric influence,[1] nothing less universal than the atmosphere itself being deemed capable of diffusing so widely the materies morbi.

On the other hand, the word "grip "(French, *la grippe*), which curiously enough was also first used in the epidemic of 1743, bears witness to the suddenness of the attack, for, although there is some uncertainty as to the derivation of this word, it comes most probably from the French *gripper*, meaning to seize or take suddenly. Other names indicating the suddenness of the seizure were "le horion" (the thump), applied to an epidemic in France in the fifteenth century, and "Blitzkatarrh," given by the Germans to another epidemic in 1781.

The predominance of catarrhal symptoms in many of the epidemics is shown by this last mentioned name, and also by the terms catarrhus epidemicus, synocha catarrhalis, febris catarrhalis epidemica, le grand rhume, etc., applied to the disease by many writers in the seventeenth and eighteenth centuries. "Russian catarrh" indicated not only the supposed nature of the affection, but also the region in which it was believed to be endemic, and from which the recurring epidemics were sent forth to visit Europe and America. An obstinate cough was a noticeable sequel to the disease in many of the epidemics, hence we find the names "tussis russa," "epidemic cough," "febris thoracica," "quinte," "coqueluche," "Schafhusten," etc.

An evil conscience is one's first accuser, and herein lies the reason why men have always regarded epidemics as the chastisements of an offended deity. And it is only within a short time that we have learned that sins against sanitary laws bring more speedy, and just as certain punishment as do offences in the moral order. The sufferers from influenza were of course, on the lookout for the sin which had brought the visitation upon them, and they usually found it, their only difficulty being in pitching upon the one sin most deserving of chastisement among the many to which they were given. In one epidemic occurring in Paris, which was called "the blow," it was believed that those only were attacked who had sung an indecent song that had happened to have a great popularity just before the outbreak of the grippe. So the poor sufferers had not only to endure the pains and discomforts of the disease, but also the jibes and reproaches of their dear friends for having been found out in the sin of singing the obscene ditty. History does not state that anyone regarded himself as unjustly punished for an offence he did not commit, and very likely there was none such.

There were many other names than those we have mentioned which were applied to the influenza in one epidemic or another, but most of them had only a local meaning, the significance of which has been lost to us. Among these we find the "dunce's malady," "pumpkin disease," "polite sickness," "Spanish pip," "new delight," "petite poste," "folette," "coquette," "the general," "fashionable fever," "turning disease," "flosse kolen," "Bürzelen," and "disease of the bald-heads." In the island of Martinique it was thought that the disease had been brought by the French soldiers, whence it was called "le chapeau quarré." Often the people gave up in despair any attempt to find an appropriate name for the affection, and called it simply "the epidemic," "the disease," "the disorder," and the like, terms about as definite and descriptive as "it," which was the appellation chosen by a medical writer in a neighboring city in a recent contribution to one of the New York dailies.

[1] This is the most commonly accepted explanation of the term, though some authorities refer it to a supposed influence of the stars, and the older Italian writers describe the disease as "una influenza di freddo."

A DISPENSARY PHYSICIAN'S RESPONSIBILITY.

Judge Roger A. Pryor, in his charge to the jury in a recent malpractice case, touched upon some points which are of especial interest to dispensary physicians. The plaintiff in the suit was a free patient who had been attended by the defendant for a miscarriage, and who claimed that she had not received proper attention from the physician and had suffered in health in consequence. The doctor visited his patient on the day of the miscarriage and on the two succeeding days, but never came afterward. It was claimed that the patient was still sick

and that the physician had no right to cease his attendance until she was cured. The Court held that when a physician engages to attend a patient without limitation of time, he cannot cease his visits except with the consent of the patient, or upon giving the patient timely notice so that he may employ another doctor, or, finally, when the condition of the patient is such that he no longer requires medical treatment. Of this condition the physician must judge at his peril. The defendant claimed that he had given timely notice to his patient that he was about to leave town and that she must get another physician. This was denied by the plaintiff, and it was left to the jury to decide the question of fact.

The woman was a charity patient, being treated gratuitously by the physician whom she sued, but this fact, the judge charged, could in no respect qualify the liability of the doctor. "Whether the patient be a pauper or a millionnaire, whether he be treated gratuitously or for a reward, the physician owes him precisely the same measure of duty and the same degree of skill and care. He may decline to respond to the call of a patient unable to compensate him; but if he undertake the treatment of such a patient, he cannot defeat a suit for malpractice, nor mitigate a recovery against him, upon the principle that the skill and care required of a physician are proportioned to his expectation of pecuniary recompense. . . . Even though, therefore, the defendant was not to be paid for his attendance, he was still bound in law to treat the plaintiff with the requisite skill and the requisite care."

But the patient has obligations as well as the physician, and in this case the woman had disobeyed the orders of the doctor to keep quiet and had risen from her bed and gone into another room. Concerning this fact it was charged that the patient must obey the orders and follow the directions of the physician, and that she could not hold the physician responsible for the consequences of any disobedience or failure to follow such directions. And in this case, therefore, Judge Pryor charged the jury that they should find for the defendant if the evidence showed that the plaintiff's own neglect or carelessness concurred in causing her injury. He also charged that a careful distinction should be made between the results of the miscarriage and those of treatment. The physician was in no way responsible for the miscarriage but only for his management of the case subsequently. It was for the jury to determine whether the injuries of which the patient complained were due to the miscarriage or to maltreatment by the doctor, and if they were due to the former solely then the verdict must be for the defendant, since he could make no contract to cure, but only to exercise due skill and care in his treatment of the case.

It seems to us that this ruling was a fair one. A physician must, of course, give proper attention to his patient, and treat him with due skill, and the size of the prospective fee makes no difference in this regard. But, on the other hand, and this is a point, we think, that is not always sufficiently insisted upon, the patient must do as he is told or he cannot claim damages for maltreatment. If this were more generally known and insisted upon there would be fewer malpractice suits, and patients might also be more careful to obey to the letter the injunctions of their medical advisers—a double gain to the hard-working physician.

News of the Week.

Poisoning by Wild Parsnip.—It is reported that twelve children were poisoned one day last week, in a Pennsylvania town, by eating the root of the wild parsnip plant which they found in a field where they were playing. Three of the children died in convulsions.

An Ossified Man Broken.—An ossified man, who had been exhibited in many places around the country, was being carried up-stairs in his home in this city the other evening when the cot was tipped up a little and he rolled off down the steps. When picked up it was found that he had fractures of the right thigh, left leg, and index finger of the right hand.

Dr. Marcus S. Hayne, of Unionville, N. Y., died in that town on April 8th, seventy-five years of age. He was graduated from Geneva Medical College just fifty years ago, and was one of the oldest members of the Orange County Society. For a number of years he held the office of postmaster in Unionville.

A Proposed Pan-American Medical Congress.—Dr. Charles A. L. Reed, of Cincinnati, has indicated his intention to introduce at the meeting of the American Medical Association at Washington, resolutions to the following effect, viz., 1. That the American Medical Association extend an invitation to the profession of the republics and colonies of the western continent to assemble in this country in an International American Medical Congress. 2. That the Committee on Nominations be instructed to nominate one member for each State and Territory and one each for the Army, Navy, and Marine Hospital Service, to constitute a committee to which shall be referred the time, place, and permanent organization of the proposed congress. Dr. Reed argues that there are sound reasons why such a congress should be held. Learning always follows in the wake of commerce. The development of politico-commercial relations between this country and those of Latin America must be followed by interchange of literature and science. Medicine will be pushed forward by necessities arising out of commerce. The questions of naval hygiene, quarantine, epidemiology, etc., arouse a communal interest between the countries of the two Americas on all subjects which could come before a medical congress. Interests of medical education might also, he believes, be reciprocally conserved by bringing the Anglo-Spanish profession closer together. Dr. Reed's personal correspondence with distinguished medical men of Central and South America shows the existence of a favorable disposition there toward the proposed congress.

The Kansas Medical College has graduated a class of twenty-three.

The Bellevue Hospital Medical College Commencement was held in the large hall of the Carnegie Laboratory on March 30th. There were one hundred and fifty-two graduates, and the address to the class was made by Professor A. A. Smith. A reception followed the exercises. On the evening following occurred the annual dinner of the Alumni Association of the College at the Hotel Marlborough.

The Sale of Tuberculin Forbidden.—The Bavarian Government has forbidden the sale by druggists of tuberculin, in Bavaria. Even physicians cannot buy it.

Meetings of State Medical Societies in May.—The Medical Society of the State of Washington, Seattle, May 6th, 7th, and 8th; Missouri State Medical Association, Excelsior Springs, May 12th, 13th, and 14th; Indiana State Medical Society, Indianapolis, May 13th, 14th, and 15th; Kansas Medical Society, Wichita, May 13th, 14th, 15th, and 16th; Illinois State Medical Society, Springfield, May 19th, 20th, and 21st; West Virginia State Medical Society, Fairmont, May 20th, 21st, and 22d; North Carolina State Medical Society, Asheville, May 26th, 27th, and 28th; Connecticut Medical Society, Hartford, May 27th, 28th, and 29th; Kentucky State Medical Society, Lexington, May (date to be fixed).

A Question of Anatomy and Expert Evidence.—A physician of Trenton, N. J., was recently adjudged guilty of contempt of court for refusing, when on the witness stand, to answer the question: "How many ribs are there in the human body?" The doctor insisted that it was a technical question, which he was not obliged to answer, because he had not received a fee for expert evidence. His counsel sustained him in the position, but the judge decided that the reason for declining to answer was not good.

Medical College Commencements.—There have been so far 33 college commencements, with 1,384 graduates: Buffalo University has graduated a class of 83; Taylor University, 13; Texas Medical College, 2; Omaha Medical College, 8; Rush Medical College, 189; Georgia Medical College, 53; Detroit Medical College, 48; Tennessee Medical College, 18; Columbus Medical College, 40; The Chicago Woman's College, 30; South Carolina Medical College, 15; Marion Sims Medical College of St. Louis, 35; National Medical College, District Columbia, 24; St. Louis Medical College, 68; The Atlanta Medical College, 80; Michigan College of Medicine, 27; Georgia Woman's Medical College, 7; The Iowa University Medical College, 21; The Kansas City University Medical College, 30; Grant University Medical College, 13; Keokuk Medical College, 3; The Southern Medical College, 36; Long Island College Hospital, 82; Fort Wayne College of Medicine, 13; The St. Louis College of Physicians and Surgeons, 68.

American Association for the Advancement of Physical Education.—The sixth annual meeting of this association was held in Boston, April 3d and 4th, Dr. D. A. Sargent presiding. Numerous papers were read, and one hundred and sixty new members were elected. The next annual meeting will be held in Baltimore.

Politics and Tuberculin.—The editor of *The Post Graduate* says there seems to be some politics in tuberculin, Professor Virchow representing the Liberal and anti-Reichstag side, and the adherents of the Hohenzollern family the other. We hardly mean this seriously, but that is somewhat the appearance this subject presents, looked at from three or four thousand miles away.

The Medical Education Bill has been defeated in the Missouri Legislature.

The Fifty-ninth Annual Meeting of the British Medical Association will be held at Bournemouth on Tuesday, Wednesday, Thursday, and Friday, July 28, 29, 30, and 31, 1891. The President is Dr. W. F. Wade, of Birmingham. An address in medicine will be delivered by Thomas Lauder Brunton, M.D., F.R.S. An address in surgery will be delivered by John Chiene, M.D., F.R.C.S. Ed. An address in public medicine will be delivered by Edward Cox Seaton, M.D.

Koch's Remedy Abandoned.—The Medical Faculty of the University of Bonn has abandoned the use of both Koch's and Liebreich's "remedies" for tuberculosis.

Another Death from Typhus Fever occurred at the New York Hospital on April 12th. The patient was a homeless and friendless Hungarian, who had been in this country but two months, and who doubtless brought the infection with him from abroad, probably from Hamburg.

An Outbreak of Tuberculosis among cattle in Putnam County, this State, has excited some alarm and awakened the activity of the local and State health boards.

The National Association of Railway Surgeons will convene at Buffalo, N. Y., Thursday, April 30, 1891. This is a change of one week from the time previously announced, the change having been made so as not to conflict with the dates covered by the meeting of the American Medical Association.

At the last Meeting of the Trustees of the Journal of the American Medical Association, it was resolved to move the Journal from Chicago to Washington. By subsequent resolution, however, it was determined to leave the matter open until a vote could be had by the members at the May meeting.

Dr. Roswell Park has, it is stated, accepted the chair of Surgery in the Rush Medical College, Chicago.

Dr. Joshua Otis Stanton, one of the best known physicians of Washington, died suddenly, April 9th, of pneumonia superinduced by the grip, after a very brief illness, aged fifty-three years. Dr. Stanton was a native of New Hampshire, and graduated in medicine from Bowdoin College. He went to Washington in 1861, and served throughout the war, rising to the rank of Major.

Dr. Hiram H. Hitchcock, of Highland Falls, N. Y., aged thirty-three, died suddenly of heart disease April 9th.

Body-snatching.—From Wheeling, W. Va., comes the unpleasant news that a reputable local physician, Dr. John R. Pipes, has been accused of body-snatching. We trust the charge is not true. Body snatching is an unpleasant business, and argues a certain unfortunate disproportion between natural sensibility and anatomical enthusiasm. In olden times body-snatching was in a measure necessary, and when judiciously carried out upon the bodies of those who died without relations, was a help to science. At present there is no excuse for it in most States.

The Roll of the Medical Profession.—The annual register of British physicians shows a total of 29,163 names. Since the previous year 467 have died, giving a mortality rate of 15 per 1,000, two names were erased for non professional conduct, and only seven retired from practice. Doctors all die in the harness.

Reduced Fare to American Medical Association.—The Baltimore & Ohio Railroad will sell round trip tickets to delegates and their friends who will attend the Annual Convention of the American Medical Association at Washington, in May, at rate of one and one-third fare. Delegates travelling via Baltimore & Ohio Railroad can obtain reduced rates of transportation by securing from the ticket agent from whom they purchase their tickets to Washington a certificate certifying to the amount paid and the route travelled. This certificate, when countersigned by the railroad representative who will be present at the Convention in Washington, will enable the holder to procure a ticket for his return journey at one-third the regular first-class limited fare.

Hospital for Contagious Eye Diseases.—The following is awaiting its passage before the New York Legislature: An act to provide for a hospital for the treatment of contagious eye diseases in the city of New York. It authorizes the Board of Estimate and Apportionment to furnish a building for such hospitals, situated not south of Fourteenth Street nor north of Fifty-ninth Street, and not to exceed $100,000 in price if the building is purchased, or a rental of not to exceed $5,000, if rented. A building may be constructed for such hospital, the cost of which shall not exceed $100,000. There shall be a board of managers of such hospital, consisting of seven doctors, to be nominated by the Council of the New York Academy of Medicine and appointed by the Mayor. The hospital is to be under the general care of the Health Department, which shall provide for the necessary attendants, supplies, etc. There shall be two house surgeons to be appointed, at $50 a month each, who shall be in constant attendance at the hospital. The Health Department shall include in its annual estimates to the Board of Estimate and Apportionment the expense of conducting this hospital, and such Board is directed to allow the same under their rules. The Comptroller shall issue bonds, when directed by the Board of Estimate and Apportionment, for the cost of the building. Introduced by G. P. Webster, Int. No. 1,044. Referred to Cities Committee.

Congress of American Physicians and Surgeons.—The meetings of the Congress of American Physicians and Surgeons will be held in Washington, from 3 to 6 P.M., September 22, 23, 24, and 25, 1891. William Pepper, Chairman of the Executive Committee.

National Board of Medical Examiners.—At the suggestion of Dr. William Perry Watson, Secretary of the New Jersey Board of Medical Examiners, Dr. Rauch has called a meeting of one or more representatives of the various medical licensing boards in the United States, to be held in Washington, D. C., on May 6th, at the time of the meeting of the American Medical Association, in order to effect a permanent organization and to make their rules and examinations as uniform as possible. Licensing boards now control medical practice in twenty-one States. It is expected that much good will come of this meeting.

A Blow at Dime Museums.—A bill is before the Pennsylvania legislature "prohibiting the exhibition of physical deformities, infirmities, and maladies as a source of pecuniary gain." We doubt very much the wisdom of such a bill. The desire of ordinary humanity to see the freaks of Nature enables many unfortunate people to gain a comfortable livelihood. The fat man, the giant, the pigmy, the lady with a horse's mane, the girl who sews with her toes, and the ossified man are probably incapable of supporting themselves by any of the ordinary means. Without the dime museum or the travelling show they would lead a dependent and perhaps impoverished existence. As objects of public interest they not only earn a livelihood but probably experience a certain degree of pleasure in the wonder they excite. This may not be a very high type of feeling but it is innocent and perhaps it is even less harmless than that which the belle feels over her figure or the beau over the fit of his clothes, or the politician over the newspaper glorifications of his statesmanship. We incline on the whole to take the part of the Dime Museums and the freaks. There should at the most be only a prohibition of such deformities as are physically painful, or of such as are produced artificially for purposes of show.

Charges Against American Physicians.—*Punch*, in a pathetic little poem anent the life of the physician, speaks of

"Living hysterical scandals down"

as one of the concomitants on medical practice. Dr. Lovelady, of Nebraska City, appreciates this fact, for he has just been acquitted of a charge of criminal assault brought by a hysterical girl. He is the fifteenth American physician so acquitted in as many months.—*Medical Standard.*

The Grip has continued to prevail in this city with but little apparent abatement, though with only moderate severity. Its reappearance in England is now reported.

Dr. Thomas H. Manley, of this city, has been appointed the New York examiner of candidates for service as internes in the Mercy Hospital of Pittsburg, Pa.

Patent Medicine Legislation Killed.—The Delaware bill, forbidding the sale of patent medicines unless the formulæ employed in their composition be printed on the wrapper, has been defeated.

The Wisconsin Legislature is not very favorable to the medical profession. All medical practice acts have been defeated, and the bill providing for coroners' expert fees will share the same fate.—*Medical Standard.*

The Nebraska Medical Practice Bill has become a law.

Progress in the South.—The Montgomery Medical Society (Ala.) has unanimously adopted resolutions favoring a consultation with homœopathists and eclectics. The matter will be brought up in the State Association, at Huntsville, May 4th.

University of Michigan.—Dr. James N. Martin has been appointed Professor of Obstetrics and Diseases of Women. He filled the chair since Professor Dunster's death.

Influenza on a Troopship.—A British troopship recently arrived at Plymouth from India, having on board a large number of soldiers whose terms of enlistment had expired, nearly all of whom suffered from the influenza during the voyage. The surgeon of the ship reported that there were two hundred cases within a fortnight, none of them, however, resulting fatally.

A Poor Field.—Scott County, Kansas, has but one physician, and he is now compelled to leave because of the following conditions: but one natural death has occurred during the past year; obstetrical cases and accidents happen but infrequently; and the atmosphere is so pure, and the people so generally healthy, that even an ordinary living cannot be made by one practising the healing art. The population of the county is given at 1,260.

The New Medical Law in Alabama.—The "Penalty Bill," which recently passed the Legislature, gives Alabama a model medical law, and places the State Medical Association on a safe and sound basis. The penalty bill, as it passed the Legislature, provides that any person practising medicine or surgery in this State, without having first obtained a certificate of qualification from one of the authorized Boards of Medical Examiners of this State, shall be guilty of a misdemeanor, and on conviction thereof shall be fined not less than $25 nor more than $100. Provided, that this act shall not apply to any doctor practising medicine in Alabama who is a graduate of a reputable medical college, and who has complied with the law by having his diploma recorded by the Judge of Probate in the county in which he is practising.

The Treatment of Influenza.—Dr. Oren Oneal, of Wabash, Ind., writes: "As this disease is again becoming epidemic in many parts of the country, and in many places is attended with great fatality, I desire to lay before the readers of the MEDICAL RECORD what I have found to be a most successful treatment. I have discarded the use of quinine, antipyrin, antifebrin, and all remedies of that class. The two latter I regard as too depressing on the heart's action, and I believe that it will be found that those who were treated with these remedies last year are the ones who are dying this spring with the second attack, with pneumonia, etc. I now rely entirely on the different preparations of ammonia, using a formula containing: Ammonii chloridi, ammonii bromidi, spts. ammonii arom., liq. ammon. acet., and syrup. Sometimes I add a little spts. frumenti. The quantities in the above formula are left to the prescriber's judgment. The effects of this treatment are often magical, all the disagreeable symptoms disappearing in a very short time."

Reviews and Notices of Books.

TEXT-BOOK OF HYGIENE. A Comprehensive Treatise on the Principles and Practice of Preventive Medicine from an American Standpoint. By GEORGE H. ROHÉ, M.D., Professor of Obstetrics and Hygiene in the College of Physicians and Surgeons, Baltimore; Director of the Maryland Maternité; Member of the American Public Health Association, and of the French Society of Hygiene, etc. Second Edition. 8vo, pp. 421. Illustrated. Philadelphia and London: F. A. Davis.

PROFESSOR ROHÉ'S book needs no introduction. The first edition was rapidly exhausted and the book justly became an authority to physicians and sanitary officers, and a text-book very generally adopted in the colleges throughout America. It is compact, of extensive scope, clearly and entertainingly written and has the special recommendation of being written by a very able man from an American stand-point. Consequently it is of unusual value to the American reader. The second edition is a great improvement over the first, all of the matter being thoroughly revised, much of it being rewritten and many additions being made. The size of the book is increased one hundred pages. The chapters on the "Germ Theory of Disease," "Contagion and Infection," and "Antiseptics, Disinfectants, and Deodorants," are unusually able and of great value. Their study will repay every reader. The chapter on "Naval Hygiene" was revised by Medical Director A. L. Gihon, United States Navy, and that on "Quarantine" by Surgeon Walter Wyman, of the United States Marine Hospital Service. These names alone vouch for their authority. The book has the additional recommendation of being a handsomely-bound, clearly-printed octavo volume, profusely illustrated with reliable references for every branch of the subject matter.

A COMPEND OF DISEASES OF CHILDREN, Especially adapted for the Use of Medical Students. By MARCUS P. HATFIELD, A.M., M.D., Professor of Diseases of Children, Chicago Medical College; Physician to Wesley Hospital, etc. With a colored plate. Pp. 185. Philadelphia: P. Blakiston, Son & Co.

THIS is one of Blakiston's very excellent series of Quiz-compends. It is based on Kormann's well-known work and supplemented by the author's knowledge, gained after a long and successful practice. Students and even practitioners will find it a valuable little book.

THE "J. E. M." GUIDE TO DAVOS-PLATZ. Edited by J. E. MURDOCK, F.R.G.S. Member of the French Alpine Club, with Analytical Notes on the Food, Air, Water, and Climate, by Phillip Holland, Analytical Chemist, etc. Fourth Edition, brought up to date. Pp. 154. Illustrated. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited.

AHE book is a very complete guide to the now famous Elpine resort so much in favor among consumptives. Tverything that a patient would want to know is given not only accurately and concisely, but in a very entertaining manner.

MEDICAL NURSING; LECTURES DELIVERED IN THE ROYAL INFIRMARY, GLASGOW. By J. WALLACE, M.D. Physician to the Royal Infirmary and Lecturer on Medicine, Queen Margaret College, Glasgow; Honorary Associate Grand Prior of the Order of St. John of Jerusalem in England, Fourth Edition. Pp. 224. James Machelhose & Sons, Publishers to the University, Glasgow.

THIS handsome volume has had a deserved popularity, and now reaches its fourth edition. It consists of a series of lectures on the principles and methods of nursing. It is invaluable to the nurse, and its chapters on disinfection, care, and ventilation of the sick room will be found exceedingly useful to the physician. Like all work of the Machelhose press it is a model of typographical art.

LEHRBUCH DER ALLGEMEINEN UND SPECIELLEN PATHOLOGISCHEN ANATOMIE FÜR AERZTE UND STUDIRENDE. Von Dr. ERNST ZIEGLER, Professor der pathologischen Anatomie und der allgemeinen Pathologie an der Universität Freiburg in Baden. Zwei Bände. Sechste neu bearbeitete Auflage. Zweiter Band. Specielle pathologische Anatomie. Mit 435 theils schwarzen, theils farbigen Abbildungen. Jena: Gustav Fischer, 1890.

THE last edition of this well-known treatise once more attests the diligence and good judgment of its author. Ziegler's pathology is probably now the leading work on this subject. The illustrations really illustrate, and the text lacks the customary verbosity of German authors. Long theoretical discussions on moot questions do not clog the pages of this practical text-book.

Transactions of the Mississippi State Medical Association for 1889

The papers presented cover the usual range of topics, and show that our Southern brethren are fully abreast of the times. The paper on "Fever, with Special Reference to Thermogenesis," is worthy of special mention.

Practical Examination of the Urine. By James Tyson, M.D., etc. Seventh Edition. Philadelphia: P. Blakiston, Son & Co. 1891.

No physician needs to be told of the necessity of having this book at hand for constant reference. It easily holds first place among the many manuals of its class. Seven editions are its most eloquent defence. The use of two sizes of type in the present volume still further improves its value as a working book.

The Treatment of Consumption by Koch's Method. By A. E. Bridger, M.D., etc. London: John Hogg. 1891.

In these pages, which can be read in an hour, the author describes his journey to Berlin, what he saw there, his observations of nearly two hundred and fifty cases, and, lastly, his personal experiences as a tuberculin patient. Titles of chapters are: "The Enemy, the Bacillus Tuberculosis;" "The Champion, Dr. Koch;" "The Arena and the Combat;" "Success or Failure," etc. From this it is seen that the book is written for patients rather than for physicians. He does not regard the bacillus in the same etiological light as does Koch. His figures and statistics do not materially differ from those which have been published elsewhere. He believes in the remedy, but would confine its use to those cases in which there is comparatively little disease. A cavity does not necessarily contraindicate its use if the pulmonary tissue remaining is in a fair state of preservation. His ideas concerning the proper care of a case, apart from the injections, are eminently sensible. Dr. Bridger's pages are rather attractive reading, though his conclusions differ in certain particulars from what is generally accepted.

Wood's Medical and Surgical Monographs. February number. Contents: "The Clinical Use of Prisms and the Decentering of Lenses," by Ernest E. Maddox, M.B.; "Electricity in the Treatment of Uterine Tumors," by Thomas Keith, M.D., LL.D. Edin., and Skene Keith, F.R.C.S. Edin.; "Ether Drinking, its Prevalence and Results," by Ernest Hart, Editor of *British Medical Journal*. Pp. 512. New York: William Wood & Co.

The table of contents of the February number of Wood's popular monographs is evidence that the book is a valuable addition to medical literature. The subjects are of practical value, and the authors are men of international reputation. The article on "Electricity in the Treatment of Uterine Tumors" is a report of one hundred and six cases treated by Apostoli's method. The results are remarkable, and the article is deserving of careful consideration.

Principles of Surgery. By N. Senn, M.D., Ph.D., Milwaukee, Wis.; Professor of Principles of Surgery and Surgical Pathology in the Rush Medical College, Chicago, Ill.; Professor of Surgery in the Chicago Polyclinic; Attending Surgeon to the Milwaukee Hospital, etc. Illustrated with 169 Wood Engravings. Pp. xiii., 611. Philadelphia and London: F. A. Davis.

This is Dr. Senn's greatest work. He recognized the need of a modern work on the principles of surgery in the English language. Progress in the knowledge of the etiology and pathology of surgical diseases has been so rapid in the past decade that recent works on the subject are not up to the times. In the matter of practical information, as, for instance, the symptoms of any particular disease, they may be exceedingly complete and valuable; but in treating of the fundamental principles of the art, and the science of surgery, they are wofully deficient. Dr. Senn has supplied the deficiency. He has given the profession the principles of surgery, and one who has mastered these will have no difficulty in applying his knowledge in practice. One gratifying feature of the book is one that characterizes all of Dr. Senn's works—originality. He is not satisfied with other men's observations, but gives the results of his own experience. Sometimes they are startling and out of the beaten path of general teaching, but they are always sound and scientific. He is recognized as one of America's leading experimental surgeons and has given to the profession much that is valuable. Prominent is his method of lateral anastomosis in resection of the intestines. Dr. Senn is an eminent bacteriologist, and his chapters on pathogenic bacteria showing their connection with the etiology of surgical inflammation, are unusually interesting and valuable. The work is exceedingly practical, as the chapters on the treatment of the various conditions considered are based on sound deductions, are complete, and easily carried out by any painstaking surgeon. Asepsis and antisepsis are exhaustively treated. All in all, the book is a most excellent one, and deserves a place in every well-selected library.

A Compend of Gynæcology. By Henry Morris, M.D., Late Demonstrator of Obstetrics and Diseases of Women and Children in the Jefferson Medical College, Philadelphia, etc. With forty-five illustrations. Pp. 178. Philadelphia: P. Blakiston, Son & Co.

Quiz compends, though condemned by a great many, are nevertheless of great value and assistance to the student preparing for examination, and to the systematic reader. Of the many series of compends none are better nor more popular than Blakiston's, of which the volume in review is a worthy representative. It is clear, concise, and well written.

An Illustrated Encyclopædic Medical Dictionary. Being a Dictionary of the Technical Terms Used by Writers on Medicine and the Collateral Sciences, in the Latin, English, French, and German Languages. By Frank P. Foster, M.D., Editor of the New York Medical Journal. With the collaboration of William C. Ayres, M.D., New Orleans; Edward B. Bronson, M.D., New York; Charles Stedman Bull, M.D., New York; Henry C. Coe, M.D., M.R.C.S., L.R.C.P., New York; Andrew F. Currier, M.D., New York; Alexander Duane, M.D., New York; Simon H. Gage, Ithaca, N. Y.; Henry J. Garrigues, M.D., New York; Charles B. Kelsey, M.D., New York; Russell H. Nevins, M.D., New York; Burt G. Wilder, M.D., Ithaca, N. Y. Volume II. With Illustrations. New York: D. Appleton and Company, 1890.

Those whose pleasure and good fortune it has been to be the possessors of the first volume of this grand work have been looking forward with considerable impatience to the appearance of the second volume, and now that they have the second they are in no measure satisfied, but are even more impatient for those that are to come, so that they may possess the perfect work. We described briefly the character of the undertaking in our notice of the first volume, and need only repeat here what we said then as to the excellence of the work, for surely no educated or cultured physician can afford not to have on his shelves this standard dictionary. The work is certainly unique and without a parallel in medical literature in any language. The present volume includes the words from Cacothanasia to Fasay, and is profusely but judiciously illustrated. In addition to the wood engravings it also contains a beautiful colored plate, drawn by Mrs. Gage, showing several varieties of epithelium.

We hope the day is not far distant when we may be enabled to congratulate the learned editor upon the completion of his stupendous undertaking.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 6, 1891.

GEORGE L. PEABODY, M.D., PRESIDENT, IN THE CHAIR.

Chronic Purulent Otitis.—DR. SEXTON read a paper on "Chronic Purulent Disease of the Middle Ear." The writer alluded to the fact that the reforms in general surgery had now come to be recognized in the treatment of all ear diseases, when such were applicable, and that the old tentative and expectant modes of treatment were fast disappearing. This fact was to a great measure owing to the introduction of the electric light for the purpose of illuminating the ear, and by the aid of which diagnoses were rendered more certain. The indiscriminate use of powders and other medicaments were not warrantable in the great number of cases and inflicted much harm as a rule. Inflammation of the mucous surface of the middle ear tract differed from that of other air-tracts in the fact that when the secretions in the drum are excessive the difficulty of escape therefrom is a very important factor.

Chronic purulent middle-ear inflammation is a sequence of the acute process in the middle ear and usually occurs in run-down subjects, or in those residing among bad hygienic surroundings, etc. Scarlet fever, measles, severe head colds, etc., are causative, and in many cases phthisis, syphilis, or some dyscrasia have their influence in prolonging the disease. In examining the tympanum in these cases we shall often find perforations of different sizes in the drum membrane, and in many it will be entirely absent. In others a cicatricial reproduction of the drumhead will be seen, stretching itself over the inner wall of the tympanum and shutting off free drainage from the attic or upper chamber of the tympanum. Sinuses frequently exist in the membrana flaccida, leading into the attic and by means of which some of the secretion may escape. The ossicles are frequently displaced or are absent altogether. These bonelets are very often affected with caries. The deformities of the sound-transmitting apparatus and tympanum arising from chronic purulent disease are innumerable. Polypoid growths and granulations are frequently present, sprouting from the atrium or attic, and serve to block up and confine secretions.

Simple chronic purulent otitis media is not very frequent and has a tendency to spontaneous recovery, but when the attic is affected the tendency does not exist. The "attic" cases, so-called, are made important from the great danger of pent-up secretion, since the drainage is usually through one small sinus in the flaccid membrane. When this outlet becomes blocked up from swelling of the tissues in acute exacerbations, etc., the result may be attended with severe danger to the patient. The pent-up and confined secretions are a continual source of irritation and annoyance to the patient and add not a little to the poor condition of the general health. Deafness, tinnitus aurium, pain, autophonia, and vertiginous symptoms are usually present, one or all, to a greater or less extent.

In the treatment of cases of chronic purulent middle-ear disease, a large field for sound judgment is offered the general practitioner, as many cases of these troubles, especially among children, come under his observation. Mild cases should be let alone, and the use of medicaments, astringents, etc., excluded as meddlesome and aggravating to the case. Too frequent use of the syringe is also inadvisable, since humidity favors the growth of granulation tissue. Attention to the general health, etc., is of great importance. Granulation tissue and polypi should be cut away where they exist. When irreparable destruction of the sound-transmitting mechanism exists the organ is at best a defective one and extremely liable to constant recurrent invasions of purulency from colds, etc., and in such cases the diseased structures should be entirely removed, thus insuring good drainage. Improvement in hearing usually follows the procedure. The operation of removing the remnants of the drumhead and diseased malleus and incus (if present) is particularly indicated in "attic" cases. In such the usual local remedies and treatment are of little or no avail, and no time should be lost with temporizing methods of treatment. The operative removal of the carious ossicles, etc., is no longer a new procedure, since it has been successfully advocated by some of the most celebrated otologists of our time, both in this country and in Germany, where it was first introduced by Professor H. Schwartze, thirteen years ago. The writer uses an electric head-lamp on the forehead, for operating. The patient is deeply anæsthetized. The remnants of the drumhead are cut away around the periphery, the incudo-stapedial articulation is divided, as also the attachment of the malleus. The latter and the incus (if present) are then removed with a dressing-forceps or foreign-body forceps. Hemorrhage is slight as a rule and can easily be controlled by syringing with hot water. In a few weeks or months the walls of the tympanum become dry and covered with a non secreting, glistening, cicatricial membrane.

The operation is one entirely devoid of danger, no case of serious results having ever been reported from the many operations undertaken here and abroad. On the contrary, the results have been most gratifying and in accordance with those obtained in general surgery since the adoption of thorough drainage and antiseptic methods.

Thrombosis of the Lateral Sinus.—DR. R. F. WEIR said he had hoped the author would have found space in his paper to consider some of the complications of purulent otitis, as these, from a surgical stand-point, were of intense interest. It had not been long since abscesses of the brain, of ear origin, had come to be recognized and successfully treated. Very recently another complication of purulent otitis had been recognized and treated, and it was that which he had hoped the paper would touch upon. He referred to thrombosis of the lateral sinus. Many fatal cases classed under meningitis excited by aural disease had been found at post-mortem to be due to infective thrombosis of the lateral sinus. Recalling his experience when in the aural department of the New York Eye and Ear Infirmary, he there, on many occasions, trephined the mastoid, and in three instances unintentionally opened the lateral sinus. In two there was hemorrhage, but it was easily controlled. In the third one, to his surprise, bleeding did not take place, yet he was manifestly within the lateral sinus. The explanation had not occurred to him until recently he had read articles in the *Lancet* (by Balance and Lane), who had shown that chills and delirium alternating with stupor and high temperature, heretofore regarded as suppurative meningitis of aural origin, must be interpreted as thrombosis of the lateral sinus. Last spring Balance reported six cases, in four of which he brought about recovery by prompt surgical interference, boldly trephining down on the lateral sinus, exploring it a distance, and proving there was a thrombus. Furthermore, to prevent subsequent infection of the lungs, he deliberately ligated the jugular vein, and washed out the sinus from above downward, through an opening made into the vein above the ligature, or through this opening upward and out, at the point of trephining.

Dr. Weir said it so happened that when he was sick last spring he was asked by a physician to see a case of ear trouble, but, being unable to go, he asked Dr. Abbe to take charge of the case for him. It proved to be a case of thrombosis of the lateral sinus from ear disease. Dr. Abbe trephined the mastoid, and, as often happened to surgeons, came down upon the lateral sinus, which, when punctured, did not bleed. There came out a quantity of foul-smelling pus. He washed out the sinus. It was doubtless a case like those described by Balance, although Dr. Abbe did not ligate the jugular vein. There was an

abscess of the neck, which was also opened. The man developed inflammation of the lungs and pleura, yet he lived four or five weeks, and it was thought he would recover, when another abscess formed in the neck, calling for incision, and four or five days afterward he died of acute œdema of the lungs.

Within the last three weeks Dr. Weir had been asked, in the absence of Dr. Bull, to see a patient in his ward, a man who had been admitted twenty-four hours before with the history that for six years he had had a purulent discharge from the ear. Six days previous to admission the discharge had ceased, great pain had come on, with high fever and severe chills. When admitted, he passed from active delirium into stupor. Dr. Weir found a good deal of œdema behind the ear. He ventured the diagnosis of thrombosis of the lateral sinus, and trephined an inch and an eighth behind the external auditory canal, and came down immediately upon an abscess estimated to contain half an ounce of pus, some of which had escaped through the external meatus. The pus had a foul odor, and undoubtedly came from the lateral sinus. He then made an incision in the neck and secured the jugular vein. There was some bleeding, but a second ligature was tied higher up and the clot was reached. He did not wash the matter out at that time from above, because the patient's condition was desperate, and in fact he died before morning. An autopsy was not allowed.

He said he had ventured to speak of the subject somewhat at length because it opened up an entirely new field of surgical interference, in connection with long-existing purulent disease of the middle ear.

Dr. Gibney inquired of Dr. Sexton whether the operation for removal of the ossicles of the ear was in the nature of a radical operation and to what extent it improved the hearing.

Dr. Sexton replied that his first operations were undertaken simply with a view of curing purulency, but he observed that in nearly all the cases there was an improvement of the hearing. On reflection, he thought one would naturally expect that result, for on clearing out the ossicles and dense, thickened tissue within the drum sound could be condensed within the tympanic cavity, thus improving the hearing. The improvement in this direction was so marked that he would now undertake the operation in some cases for that reason alone, if for no other. He supposed it might be called a radical operation so far as removal of diseased structures was concerned, in the sense that one would speak of excision of the knee as a radical operation. Indeed, the condition resembled in considerable degree a chronic suppurative synovitis of the knee. There were sinuses, diseased structures, and imperfect drainage. He had been very much encouraged to undertake this work by the improved results obtained by general surgeons in disease of the knee, etc., since they had abandoned poultices and the like.

Improvement of the Hearing after Removing the Ossicles.—Dr. J. D. Byrant related a case which Dr. Sexton had operated upon for him, relieving the patient of noises from which she had suffered a long time, and which she thought would drive her insane. Moreover, he could say that her hearing had very much improved.

The question raised by Dr. Weir recalled to his mind the case of a physician upon whom he had operated the past summer. He had been suffering from very indefinite symptoms of inflammation of the mastoid cells. Neither the pulse nor the temperature gave any indication, but pain was present. Dr. Byrant would, in fact, not have suspected difficulty in the ear had the patient not feared it from previous experience leading to deafness on that side. He declined to operate at that time, but asked to be notified of any further signs. Three days later he received information that the patient thought there was evidence of disease, and on visiting him he followed a sinus down which led directly upon the lateral sinus. Pus was found in considerable amount around the lateral sinus. He examined with a view to discovering any thrombus, but could feel none, and then introduced the hypodermic needle, found blood, and thus satisfied himself that the sinus was open. With free drainage and cleanliness the patient recovered promptly.

Dr. Sexton, in closing the discussion, said the scope of the paper prevented mention of the subject discussed by Dr. Weir, and of cerebral troubles, which belonged rather to general surgery. Since, however, inflammation of the lateral sinus had been spoken of, he might say that it had occurred to him it might sometimes be mistaken for the condition in which inflammation sometimes extended directly downward from the mastoid cells, behind the insertion of the sterno-cleido-mastoid muscle, pus finding an outlet in the neck, sometimes in the posterior wall of the pharynx.

Tubercular Peritonitis; Exploratory Laparotomy.—Dr. Clement Cleveland related a case of tubercular peritonitis determined by exploratory laparotomy. The patient, twenty-four years of age, married three years, entered the Woman's Hospital about ten days ago. Two years ago she had given birth to a healthy child. She had herself always been in good health until last October, when she noticed that her abdomen was growing larger, and that there was pain in the lower abdominal region. Soon afterward she began to suffer from dysmenorrhœa. She sought the advice of a physician, who prescribed for her without making a diagnosis. On February 13th a doctor from a neighboring town was called in consultation, who thought he could make out a tumor, made exploratory puncture, and withdrew, the patient stated, about a teaspoonful of straw-colored fluid.

A thorough examination was made of the lungs and heart after she entered the hospital but no evidence of disease was found. Dr. Cleveland examined the abdomen, observed bulging, but there was only indistinct evidence of fluid, except by percussion. The resonance extended down some distance in the iliac region on both sides, there was flatness in an irregular line up to the umbilicus. Examination per vaginam showed the uterus to be retroflexed, firmly bound down by adhesions. By bimanual palpation he obtained indistinct evidence of fluid. The temperature had been taken night and morning for a week, and only on one occasion was there a slight rise. He made a diagnosis of tubercular peritonitis or of collapsed cyst, and asked the advice of several associates. They concurred in the diagnosis, and in the opinion that an exploratory incision had better be made. If there was no tumor, but tubercular peritonitis, the patient would obtain relief for several months by the operation, as the history of a number of cases had shown. He operated the Monday previous, making rather a short incision at first. Some fluid gushed out; the peritoneum was rather thick. He enlarged the opening; a quantity of fluid escaped. Beneath the incision was an obscure mass. The patient was then placed in Trendelenberg's posture and the rest of the fluid flowed out. Then he was enabled to see the contour of the abdominal cavity. It was largely shut off by the intestines, which were adherent to the parietal peritoneum in about the lines indicated by the percussion-note over the abdomen. Tubercular nodules existed everywhere. He washed the cavity out very thoroughly, sewed up the peritoneum and abdominal wound, and the patient had given an uneventful history since.

Semmola on Koch.—Professor Semmola, of Naples, does not give his sanction to experiments with Koch's lymph. He has recently delivered a lecture in which he said that the rational treatment of tuberculosis is to attempt to modify the predisposition to the disease, which the lymph does not do. Neither does it kill the bacilli nor render the soil unsuitable to their multiplication. "The first precept of medicine is, *Ne nocent*, yet in this case men have played with the lives of their patients by giving a certain poison in order to obtain a problematical alleviation."

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 23, 1891.

ORLANDO B. DOUGLAS, M.D., PRESIDENT, IN THE CHAIR.

Medical Men and the Secular Press.—DR. FREDERICK R. STURGIS read a paper upon the question, "Under what Circumstances and to what Extent may Members of the Medical Profession properly Permit their Names and Opinions to be Published by the Secular Press?" The author read that portion of the Code of Ethics of the American Medical Association, and that of the Medical Society of the State of New York bearing upon this question, and entertained the view that the former was more practical and liberal in this regard than the latter. But there was nothing in either Code that prevented a member from publishing his name, place of residence, and office hours in the public press. This was often done in country places. It was the speaker's individual opinion that there could be no more harm in calling attention to the fact that one made a specialty of a certain class of diseases than that he treated all classes of diseases, nor did he think it would reflect upon or injure the dignity of the profession. There was one section in the Code of the State Society which he thought would, sooner or later, require modification, namely, the one relating to the opinion of medical men published in the public press through the medium of reporters, etc. It was sometimes extremely difficult for a physician to refuse to express an opinion on subjects which were attracting great public attention. If he did not, he would be likely to find an opinion put into his mouth which was foreign to what he would have freely expressed had there been no restraining Code of Ethics. He believed that if a newspaper wanted an opinion from a medical man it would get it, by "hook or crook," and it seemed to him better that the physician should state his views than that they should be misstated without his consent. He was well aware, however, that this opinion might meet with opposition on the part of some of the profession. Reference was made to the sensational statements contained in the newspapers regarding the attempt at transplantation of the bone of a dog to the human subject and to the use of tuberculin, as instances in which, if the profession had been permitted to speak, much unreasonable opposition to vivisection in the one case, and false hopes as to the cure of a certain disease in the other, would have been spared.

But it was quite different with regard to allowing one's name to be affixed to a certificate regarding the value of any proprietary preparation. He could never be assured that the high quality of the preparation would be maintained.

Papers which were read bearing on the public health, hygiene, and sanitation were often quoted and the names published in the daily press, and this he regarded as perfectly proper, for such names were usually of those of high standing in the profession.

In summing up, he answered the question at the head of his paper as follows: 1, In cases where our opinions are sought on matters pertaining to public health; 2, where advice or opinion is sought with regard to new or unusual methods of treatment; 3, to correct a mistaken impression with regard to an operative procedure or method of treatment; 4, although not strictly pertaining to this subject, he might say it was perhaps permissible for physicians to advertise their names in papers, and that there would be no harm in a physician stating the fact that he treated a certain class of diseases.

A Peculiar Ailment.—DR. A. JACOBI said the symptomatology of the ailment which formed the subject of to-night's discussion was rather well known. Its etiology varied to a high degree. Its therapeutics were very uncertain. Its cure appeared to be very doubtful. For relapses, to say the least, were very frequent, and invasions in new persons, like the eruptions of infancy, were quite numerous. As usual when he spoke, he had no prescription; he would only speak of the affection on general principle. Nor had he anything new to offer, for the opinions which he had expressed in a presidential address before the Academy of Medicine were those which he yet held. With rare exceptions, general questions could not be answered by any man to the satisfaction of his fellow-practitioners or of the interested public. If the secular press was anxious to inform the public with reference to medical or hygienic subjects, there was a much more direct and successful manner than by gathering haphazard remarks from individual physicians. To write popularly on a scientific subject was difficult, and required more time than the physician could give to it even if he had the tact. If interviews were permitted, the dignity of the profession would suffer from the absurd notoriety acquired by unscrupulous self-advertisers. He believed that the newspaper which would get a thoroughly informed medical man on its editorial staff, with nothing to do but report to the public on medical discoveries, physiological and hygienic matters, in a simple and intelligible manner, would render a great service to the people and advance its own prosperity. If advertising was going to be permitted, why not do it openly, for cash? The medical profession in this country, where it was not supported by Government, required the full confidence of the people, and in order to obtain this, gentlemanly bearing and unobtrusiveness were necessary. It had been agreed that public advertising of any kind was unworthy of the profession. There was not a person who had succeeded in making himself respected by the public and the profession who had advertised.

A Matter of Taste.—DR. DANIEL LEWIS remarked that the profession owed certain duties to the community. It was its duty to inform the community when asked regarding the public health and certain other matters. But he thought the press was likely to publish matter which was really unimportant, and might even do the community an injury by sensational reports concerning, for instance, the curative value of tuberculin, etc. Then, too, it was liable to misrepresent the physicians in imaginary interviews. Regarding personal advertising, he thought it was largely a matter of taste. A complaint was once made to the Committee on Ethics that a certain member of the County Society had hung his sign out on an apple-tree. The reply of the committee was that there was no law against this; it was a matter of taste; and no attention being paid to it the gentleman whose sign had hung out like that of a Chinese laundryman's soon concluded of his own accord that it was not becoming and had it taken down. And so with advertising one's name and office hours in the press. There was no law against it, but it would be in such poor taste that no one would continue it because of the injury he would himself suffer from such a course. It seemed to him common sense would regulate these matters without the profession as a body perplexing itself about them.

DR. ALEXANDER S. HUNTER called attention to the frequent errors in, and the unreliability of, the "interviews" published in the medical press. They were obtained by young men of limited education, many of whom wrote up the "interview" from memory, and the doctor was often made to appear ridiculous. He thought the public press could obtain such information as the public might need from matter published in the weekly medical press. If interviews were had, errors might be avoided if those interviewed were to take the precaution to write out what they had to say. He suggested that the Committee on Hygiene of this Society might be deputed to be the channel of communication between the profession and the public. On the outbreak of grave infectious or epidemic diseases its chairman, when convening his committee, might also invite those whose opinions he might covet. An official expression thus formulated would command the respect of the public and relieve us of the stigma of "disagreeing doctors."

He agreed with Dr. Jacobi, that all worthy specialists could advance themselves without public advertisement, as do the general practitioners. For those of the profession who had the weakness to take delight in reading their own things and methods from the public press, he asked the charitable consideration of the Society, and expressed a willingness to second a set of kindly drawn resolutions of pity for those who were thus constituted.

The Profession versus Self.—Dr. George F. Shrady said it was known that he had inveighed a great deal against what had been called advertising, and had come to be known somewhat as the champion of the modestly meritorious medical men. On the other hand, he confessed with all humility that he had been interviewed, quoted, and described by the daily press. He was in the position of the man who had a theory that when anyone was shot in the heart he would never have any reflexes, and when at last he was struck by a ball, jumped up, and said "Excuse me. My theory is sound, but I cannot help it!" He had come to the conclusion that there were two ways of medical interviewing in the daily press; a proper one and an improper one. The proper one was for the individual to speak for his profession, to sink the *ego* entirely out of sight and be proud to be spokesman for his brethren to the public. If that plan were carried out he believed we need never be ashamed of any interview which appeared in the daily press. The improper way was to magnify the *ego*, by placing the profession in the background and making it appear that by some special skill of our own we were superior to our associates, thereby creating invidious distinctions. If everyone who was interviewed on a medical subject would aim to place his profession in a properly scientific and dignified position before the public he should be proud to be its spokesman. It was often for want of manly and outspoken views on behalf of the profession that legitimate medicine suffered in the eyes of the people, and not infrequently courted the criticism of the secular press. The great trouble had been, however, in using covert means to advertise self by countenancing the reports of surgical operations, special methods of treatment, and the like. There were a great many ways in which this was done which were alike amusing and reprehensible. These modest doctors would say, "Now, Mr. Reporter, I don't want you to mention my name in connection with this business at all. It is derogatory to the dignity of the profession. It will never do. But if you really insist upon it, here is my card. It does no harm to have the name spelled correctly."

He mentioned another instance bearing upon this part of the question. A reporter on one occasion sought to be a contributor to the Medical Record, mentioning as a qualification that he was accustomed to report operations for the leading papers, and exhibited a specimen of his work already prepared for one of the dailies. "But," said the editor, "have you been allowed to do this by the principal?" The answer was, "He not only knows it, but corrects my manuscript." Subsequently, in proof of the statement, the revised report was shown and was afterward published. The victim to the notoriety was, of course, very much surprised, and maintained that the exaggerations were nothing more than could be expected from a sensational newspaper report. Thus the secular press was made the scapegoat of sneaking advertisers, and was blamed for many things of which it was innocent.

As one who had been brought constantly in contact with representatives of the press, he could testify to their fairness and desire for truth, and had often been surprised at the amount of knowledge which they had shown of medical subjects. Nor had he ever seen any particular misrepresentation by the press of remarks which had been made in a truthful and straightforward manner.

From the Stand-point of the Public Press.—Mr. Charles R. Miller, of the New York *Times*, present by invitation, said that all those who had spoken had been guilty of the same offence, of having been interviewed, and therefore it would appear that there was only one side instead of two sides to this question. He thought there were at least three occasions when the public had a right to demand the opinions of medical men. One was when, like during the recent excitement regarding Koch's lymph, a new remedy was introduced which was likely to arouse the hopes of a large class of sick people. Another, when an epidemic made its appearance. Again, when a Grant, a Sherman, or a Garfield was lying on his death-bed, and a reverent people looked to the profession for words of hope, or to be prepared for the end of all hope. He thought the line which separated the reputable physician from the advertising quack was not so frail that the public would not distinguish the blatant advertising of the latter from the conscientious interview with the former which an interested public now and then demanded. He feared that if Dr. Jacobi's suggestion were acted upon by the press, and a medical editor were attached to their staff, the profession would soon be expressing such loud complaints that it would be necessary to ship him West.

Some Advertisers Get Honor and Money.— Rev. Dr. Buckley, also present by invitation, gave some instances showing that the Code of Ethics which prohibited advertising often made it very difficult for able men who might settle in a strange community to get along and acquaint the public with their talents, while unscrupulous quacks entered at once upon a lucrative practice. He also mentioned some instances where regular physicians had rapidly risen in honor and wealth by securing the publication of an interview or other method of advertising, thus constituting an exception to the rule as laid down by Dr. Jacobi. He thought there should be some means devised whereby the public could be informed regarding the ability of a physician who might be a stranger to them, and for the physician to make known to the public the college from which he had graduated, and the medical societies of which he might be a member.

A Broad Code.—Dr. D. B. St. John Roosa thought that when the Old Code and the New Code discussion took place in this State, and which finally resulted in the overthrow of the Old Code in as far as it prevented free consultation, it was unfortunate we did not go further. Physicians were constantly violating that part of the Code relating to interviews and the appearance of their names in the public press and he thought it might much better be wiped out entirely. Suppose the clergymen of this country, or the lawyers, should assemble and make rules as to how far their opinions upon theological or legal subjects should be presented to the public. He thought the whole Code should be done away with, and the members of the medical profession be allowed to take care of their own matters in their own way, like gentlemen.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE PROGNOSIS IN CASES OF FATTY DEGENERATION OF THE HEART, DISEASE OF THE RIGHT VENTRICLE, AND ANGINA PECTORIS — MODERN METHODS OF PERFORMING CÆSAREAN SECTION—YELLOW FEVER—SPONDYLOLISTHESIS—A UNIVERSITY FOR WALES—THE CENSUS.

London, April 4, 1891.

In the third "Lumleian Lecture" at the College of Physicians, Dr. Broadbent discussed the prognosis in cases of fatty degeneration of the heart, disease of the right ventricle, and angina pectoris, respectively. The prognosis of the first affection could contemplate, he said, only one result; a fatal termination was merely a question of time and circumstance. Excluding cases in which death had been sudden without warning, the shortest period in his experience over which characteristic symptoms had extended, together with recognized physical signs, had been about six weeks. Several patients had

survived the diagnosis two years before justifying it by dying suddenly. Circumstances as well as time entered into the prognosis; on the one hand a fatal termination might be hurried on, and, on the other hand, judicious care might postpone it till the heart was completely worn out and came to a standstill. Was fatty degeneration of the heart ever cured or arrested? If the granular disintegration which was produced by typhoid fever was to be included under the term, the answer must undoubtedly be "yes." When degeneration had been the result of other forms of blood-poisoning it ought to be possible, and now and then to occur, that recovery of the heart should follow a return to a more healthy state of blood. The lecturer then related the case of a patient in whom he diagnosed fatty degeneration of the heart ten years ago, the patient being then about fifty-five. The patient would never relinquish exercise, but continued to walk, however slowly and at whatever cost of pain and distress, every day, exercising great self-command and measuring his strength very exactly. Little by little he gained ground and was now alive and in fair health, though not capable of much in the way of work.

In the diagnosis of fatty degeneration of the heart the most constant and significant feature of the pulse was that it was short and unsustained. (Physical signs might be described as negative, but the absence of murmur, or of conspicuous modification of the sounds or intervals, and of disturbance of the relation between the two sides of the heart, or of increase of dimensions when symptoms of serious slackening of the circulation were present, and especially when there had been anginal or syncopal, or apoplectic attacks, added gravity to the case.) But a weak, short, unsustained pulse was common as a constitutional peculiarity, or might at any period of life be simply a result of general debility, and impulse and apex-beat might be entirely absent and the sounds might be short and weak. In young people there was no danger of such weakness being taken to be indicative of degeneration of the heart, but it might arouse anxiety after middle age—especially if there were also irregularity. It was important to distinguish between functional weakness of this kind and weakness arising from organic disease, and this could usually be accomplished by making the patient walk briskly. A few steps would often suffice. If the heart were sound it would rise to the occasion, whereas the fatty heart would "go to pieces" and the pulse might even disappear. The diagnosis of fatty degeneration of the heart was not easy until the disease was far advanced, and could scarcely ever be made without more than one opportunity of examination.

Speaking of disease of the right ventricle, Dr. Broadbent said it had seemed to him that our ideas had been too much based upon a study of the symptoms which attended affections of this ventricle secondary to disease of the left ventricle or its valves, which therefore were really attributable to the original disease. Undoubtedly, the supervention of dilatation of the right ventricle and of reflux through the tricuspid orifice allowed back pressure to be brought to bear upon the veins, but this only intensified pre-existing symptoms, and made no change in their character. We were perhaps justified in assuming that venous back pressure from insufficiency of the mitral valve would in some degree produce the same results whatever the state of the left side of the heart. But the conditions were fundamentally different when the tricuspid reflux was primary, for it was not impossible that a sound and strong left ventricle might come to the aid of the right ventricle, just as the right ventricle so constantly came to the aid of the left. The pressure which would cause the blood to spurt for two or three feet in venesection might carry a current through the capillaries of the lungs aided by the respiratory movements and the valves of the pulmonary artery. Dr. Broadbent said it had also seemed to him that weakness of the right ventricle, the left one being normal, had in some cases given rise to symptoms due rather to inadequate supply of blood to the left side of the heart than of damming back of blood in the veins. A few cases had come under his notice in which the right ventricle had appeared to be predominantly or almost exclusively affected by asthenia or degeneration—the effects being similar to those observed in tricuspid regurgitation. He narrated a case in which there was an entire absence of right ventricle sounds, and said he could not doubt that there was really no action of the right ventricle.

One of the most serious effects of weakness of the right ventricle was met with in disease of the mitral valve. When this valve became inefficient the right ventricle was for a time the rampart by which the reflux of blood was arrested and the crippled left ventricle reinforced. The systolic apex-murmur in mitral regurgitation gave no trustworthy information as to the amount of blood carried back into the auricle. We gathered this mainly from the effects on the right ventricle. The first of these was accentuation of the pulmonary second sound, indicating increased pressure in the pulmonary circulation; following on this came hypertrophy of the right ventricle, by means of which the obstruction to the passage of blood through the lungs was overcome. It was by the augmented strength of the right ventricle that the mitral leakage was neutralized and a working equilibrium established. The change in the right ventricle thus became a measure of the regurgitation, and therefore, when we detected a mitral systolic murmur, we at once examined the right ventricle in order to gather from its condition information as to the amount of reflux not yielded by the murmur itself. When in these cases the right ventricle was in a state of degeneration or great weakness, and symptoms of failing compensation had set in, the prognosis was extremely grave. The fulcrum for some of our most efficacious therapeutic measures was missing, for we dare not open a vein, however great the respiratory embarrassment and cyanosis; leeching over the liver was less good, and a dose of calomel was not well borne. Under such conditions recovery was rare, and the lecturer said that twice in his experience patients in whom an unfavorable prognosis had apparently been belied by apparent convalescence, had died suddenly when beginning to walk about. Similar conditions resulted from time to time from adhesion of the pericardium, for the right ventricle suffered much more than the left from pericarditis. The right ventricle was also undoubtedly sometimes the cause of sudden death, and when the heart was embarrassed or stopped by pressure upward of the diaphragm by a distended stomach or colon, it must be on the right ventricle that the pressure took effect, for this part of the heart rested upon the diaphragm and would be directly compressed when it was pushed up.

The prognosis of angina pectoris was beset with uncertainty. We could never tell when the next attack would come on, or whether it might not be the last. The elements to guide us would be an estimate of the relative predominance of the two chief factors in the production of the attack, whether inherent weakness of the heart-wall, or obstruction in the circulation, or other cause of embarrassment of the heart's action. When the attacks only came on when provoked by exertion or excitement, or by flatulent indigestion (not, of course, taking the patient's word for the last-named cause), the hope might be entertained that by care the attacks might be postponed indefinitely. The patient, for example, must not take exercise immediately after food, must never hurry or walk against a wind, even on level ground must adapt his pace to his condition, and if compelled to go up hill, must do so very gently and circumspectly. If there were habitual high tension in the pulse, there was at the same time evidence of obstruction in the arterioles and capillaries (which might be capable of mitigation) and of some degree of vigor in the heart. So also would be accentuation of the aortic second sound, and still more any recognizable impulse or apex-beat. Angina in connection with aortic valvular disease might run a protracted course. It

was when the pulse was soft, and the heart was normal in dimensions, with imperceptible impulse and weak sounds —when, in fact, the results of careful examination were negative—that the greatest uncertainty and danger existed. The occurrence of unprovoked attacks and of nocturnal angina would emphasize this conclusion.

At the last meeting of the Hunterian Society a paper on "Modern Methods of Performing Cæsarean Section" was read by Dr. Galabin, obstetric physician to Guy's Hospital. The author ascribed the high mortality—sixteen per cent. or more—of the operation at some hospitals to the adverse effect of previous attempts to deliver by forceps, etc. Säuger's method was designed to close the uterine wound by a system of deep (muscular) and superficial (peritoneal) sutures, and so keep the uterine and peritoneal cavities shut off. Success depended much on the operation being a primary choice. In a multipara one need not wait for labor to begin, but it was usually best to puncture the membranes. The use of an elastic ligature round the neck of the uterus was, on the whole, good. Dr. Galabin preferred silver wire for the deep sutures, the superficial ones being so arranged as to bring flat surfaces of peritoneum in contact. Cameron, of Glasgow, shortened the operation by using no superficial sutures, and had had only one death in ten cases. It was often advisable to sterilize the patient by removing the ovaries, or tying the Fallopian tubes near the outer end.

A steamer is now in quarantine at Southampton, in consequence of four deaths from yellow fever having occurred during the voyage from Brazil.

At the last meeting of the Obstetrical Society a specimen of spondylolisthesis was shown by Mr. Targett.

It is proposed that Wales should have a university of its own, with power to confer degrees.

In the decennial census just about to be taken, information will be asked as to the number of persons: 1, deaf and dumb; 2, blind; 3, lunatic, imbecile, or idiot.

THE DISPENSARY ABUSE.

To the Editor of the Medical Record.

Sir: In your issue of March 28, 1891, there is an article on the "Dispensary Question," signed "F. R." The writer's ideas impressed me rather favorably when reading this over for the first time, but after further consideration I concluded that there was an underlying fallacy in the argument. First, the author states that when those individuals patronize the dispensary who by making an effort could contrive to pay a physician they are no more pauperized than the visitors to our libraries, parks, and museums; and that there is a certain class of people in the community who by receiving free medical treatment are prevented from descending to the level of the tenement-house population. Now, I understand that a pauper, according to the general definition, is one so indigent as to depend on charity for his maintenance; hence the recipient of medical charity is thereby pauperized to this extent. He cannot be compared to the man who visits the libraries and museums, as these institutions are luxuries, not absolutely essential for man's maintenance, and those who enjoy their advantages cannot be considered paupers according to the definition of that word; while, on the other hand, medical treatment for the sick is a necessity. Again, why should free medical treatment be extended to the class of people mentioned, who would thereby be maintained in their present social position, any more than should the other necessaries of life be supplied to them gratuitously? The writer then goes on to say that the dispensaries are making it hard for some doctors to live, but that every new machine throws hand-workers out of employment, just as the discovery of petroleum took away the whaler's occupation; nevertheless petroleum and machinery are good things, and the doctor whose occupation is gone must find another. Now this, as far as the hand-worker and whaler is concerned, may be true, but it does not apply to the physician. What can take his place? The dispensary cannot exist without him, and his occupation, so far from being gone, is, on the contrary, in increasing demand, and always will be so long as human beings are subject to disease. The writer then adds, "Were it possible for every man, woman, and child in New York to secure medical attendance free, to be relieved from the burden of sickness, the community would be by just so much the better off." I think the author might with equal fairness argue that free groceries, free clothing, and free homes would also benefit the community. If this idea were carried out, there would be no necessity for work; the people would become demoralized, and we would soon have a nation of paupers. I believe that every right-minded physician, and also our best laymen, agree that the object of the dispensaries should be to afford medical treatment to the needy poor only.

Alpheus Freeman, M.D.

New Instruments.

AN INSTRUMENT FOR TREATING ENLARGED TONSILS BY ELECTROLYSIS.

By HENRY L. COIT, M.D.,

Newark, N. J.

The diversity of opinion concerning the wisdom of excising enlarged tonsils, together with the difficulties in obtaining the consent of patients to this operation, led the writer to devise a suitable instrument for treating these cases by electroylsis. The accompanying cut will represent the instrument, which was made for me by Messrs. Tiemann & Co., of New York, and is designed to enable the practitioner to treat hypertrophied tonsils by the electrolytic action of negative galvanism. The electrode consists of a shaft of steel, insulated throughout its entire length with a movable hard-rubber sheath. The bifurcated needle is curved so as to include the tonsillar tissue in its grasp. It is made of platinum and is insulated to within a centimetre of the points. The points are separated by pushing the steel shaft through the insulating sheath, and by means of the thumb-screw they are made to approximate each other and thereby caused to pierce the submucous tissue of the tonsil. The needle carries but one current (the negative), which is denutritive and promotes absorption of the fibrous exudation without destroying the mucous membrane. The positive pole is applied by a sponge electrode to the skin external to the affected tonsil. From five to twenty milliampères will be found sufficient, applied at intervals of one week. The operation is very much facilitated by the local application of cocaine.

The Therapeutic Value of Sodium Iodide.—It has been asserted by many that iodide of sodium was an inert substance, or at least that it exerted no medicinal action similar to that of iodide of potassium. Dr. Gingeot, of the Hôpital Saint-Antoine, has made a number of experiments to settle this question, and finds that the drug does possess undoubted therapeutic properties, equal to, if not superior to, those of the potassium salt, in cases of arteriosclerosis, though it may be less potent in cases of syphilitic disease.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 5, 1891, to April 11, 1891.

HOFF, JOHN VAN R., Captain and Assistant Surgeon, now in New York City, on leave of absence. By direction of the Acting Secretary of War, is assigned to duty as an additional member of the board of medical officers constituted by paragragh 18, S. O. 52, March 7, 1891, from this office, to meet in New York City, for the examination of candidates for admission to the Medical Corps of the Army, etc. S. O. 78, par. 6, A. G. O., Washington, D. C., April 7, 1891.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 11, 1891.

	Cases.	Deaths.
Typhus fever	2	1
Typhoid fever	9	2
Scarlet fever	228	35
Cerebro-spinal meningitis	3	5
Measles	342	18
Diphtheria	82	30
Small-pox	0	0
Varicella	6	0
Pertussis	6	20
Erysipelas	0	0
Mumps	0	0
Rötheln	0	0

Poison-Proof Animals.—Neither differences of organization in animals, nor in the constitution of the poisonous substance generally, afford any clew for interpreting an exceptional want of effect. Unaccountable is the immunity of rabbits against belladonna. You may feed them with belladonna for weeks without observing toxic cerated facial neoplasms.

The literature on the effects and on the value of external as well as internal application of the aniline dyes, especially pyoktanin (blue), in general surgery is comparatively small yet. Notes in this respect will be best found in the second treatise of J. Stilling,[1] Professor of Ophthalmology at the University of Strasbourg, Germany, who together with Dr. Wortmann, made careful bacteriological and chemical researches with the different aniline dyes. He baptized one of the methyl-violets, which showed the greatest antiseptic power, pyoktanin, and introduced two different kinds of the drug, the blue and the yellow (pyoktanin cæruleum and pyoktanin aureum). The latter is also called auramin. Its antiseptic power is far less than that of the former one; it is mostly used in superficial wounds and on the face, as it dyes the tissue yellow.

In regard to this special subject, viz., the use of the aniline dyes, especially pyoktanin,[2] in the treatment of inoperable malignant growths, only a few gentlemen have so far reported. Stilling mentions in his second paper[3] that he succeeded in curing with pyoktanin an extensive excerated epithelioma of the face (ulcus rodens) which, beginning in the middle of the dorsum of the nose, involved the entire wall of the lachrymal sac and half of the upper eyelid. He first sterilized the surface with a large pyo-

[2] In mentioning "pyoktanin" in the following notes always "blue" one is alluded to.
[3] Loc. cit., p. 96.

than in men (29.74 per cent.). Age again seemed to be a factor, for ova were detected vastly more frequently in the fæces of subjects under fourteen years of age (45.49 per cent.), while at a later period of life—over sixty—this only obtained in the proportion of 14.81 per cent. He found representatives of most of the genuses of intestinal worms, ascarids and bothriocephalus being the most common, and the tænia solium the most infrequent. During the autumn months intestinal parasites were met with more frequently than during winter and summer, but the season appeared to exercise a notable effect on the prevalence of individual varieties; thus, ascarids occurred most frequently at about the end of the summer season and during the autumn, bothriocephalus during the autumn and winter, while trichocephalus triumphed indifferently in all four seasons of the year. Respecting racial preferences, he remarks that the Hebrew race suffered rather more than other nationalities, but among all races the poor are naturally more liable to harbor these parasites than the well-to-do. As might be anticipated, particular occupations predispose to special varieties of the enemy, but the results in this respect are less conclusive. One important observation is that bearing on symptomatology. Of 306 hosts, 88 did not present any symptoms referable to the presence of the parasites, but in the remaining 218 gastro-intestinal disturbances and other nondescript symptoms were complained of. Curiously enough the vast majority of the hosts entertained no suspicion whatever of the contents of their intestinal canal, and the author points out that in all obscure cases of anæmia, emaciation, and gastro-intestinal or nervous disturbances it is eminently desirable to institute a careful microscopical examination of the fæces for the purpose of detecting the presence of ova.—*The Medical Press.*

The Pennsylvania Pharmacy Law which was passed in 1887, provided that any graduate of any accredited college who had had not less than three years' continuous practice could be registered under the act to carry on the retail drug and apothecary business without examination. The courts have decided that the Pharmacy Board has no discretionary power and cannot refuse registration to any applicant. The consequence is that the Pennsylvania Pharmaceutical Association has risen up in arms to have that part of the law repealed so that all applicants for the practice of pharmacy shall be examined. On the other hand, the doctors are working for the passage of a bill that shall leave no doubt as to whether physicians who apply for licence must be examined. This amendment reads that such doctors *shall be* registered without examination. The Pharmaceutical Association is doing active work and every druggist in the State received a strong circular urging him to write to his representative in the legislature and use all his influence to have the offending clause repealed.

The Renaissance of Therapeutics.—Dr. Spender states that, within a period of fifty years, corresponding pretty nearly to the reign of Victoria, there have been great changes in therapeutic art and practice. Some of our methods are so transformed that the art itself seems almost new, others are guided to new ends, and the scope of not a few is much enlarged. Let us go back half a century, and bring to memory (if possible) our medical poverty in and about 1840. Crying sufferers entreated us, and we could only confess our impotence to help them. Diseases were called incurable simply because we had no means of curing them. There were whole domains of work in which we seemed no better off than Scott's North Country doctor, who boasted of his "twa simples of calamy and laudamy." And we were chilled by that "therapeutic nihilism" which began in the school of Vienna, and has infected a large number of practitioners in all parts of the world. Pathology was in great fashion between 1845 and 1870, and medical energy ran strongly in the direction of necropsies and microscopes. Diag-

nosis was deified and worshipped; a post-mortem examination which showed a doctor to be right was more esteemed than a recovery which showed him to be wrong; morbid anatomy was a passport to fame. To demonstrate a disease had a more striking note of glory than ability to cure it. So recently as 1861 a New York journalist uttered the reproach that therapeusis had lingered far behind all other branches of medical research. If Nature did not surrender her secrets of healing, it was too much trouble to wrestle and make her declare them. If we were ignorant, we pleaded the parsimony of natural laws and forces. A more humane philosophy altered the whole current of professional thought. Dr. Latham declared that the treatment of diseases is part of their pathology. Sir Thomas Watson inaugurated the first meeting of the Clinical Society by an address in which he chided the profession for vagueness and want of earnestness in the use of drugs; trying one thing after another, and going about without landmarks or beacons. Sir Thomas Watson's challenge has had a most bracing effect. The laughing scepticism of the other day is out of court. We employ our therapeutic possessions as if we trusted them; we lean upon the rock of physiological experiment and steady observation. The doubter and scorner are still among us, but they lie in ambush as if ashamed.—*Practitioner.*

Getting Even with a Tape-worm.—A butcher boy treated by mercurial inunctions, having passed two solices per anum, was treated with male fern, which caused the evacuation of two tænias, whose gray coloration caused the presence of mercury to be suspected. Chemical analysis having demonstrated that such was really the case, microscopical examination gave the following result: Treated with glycerine, each proglottis showed the metallic deposit in the vas deferens, in some of the vasa efferentia, and in the vesiculæ seminales. It was so pronounced in the oviduct that even to the naked eye it presented the appearance of a dark streak. The vagina looked like a dark tube, although on section the narrowed calibre was still found to exist. The walls of the uterus also contained a certain quantity, while the ovary itself was quite free. After staining by means of eosine and other coloring matters, longitudinal and transverse sections revealed the fact that the entire parenchyma of the tænia contained particles of mercury, equally distributed. On the integument these were collected principally in the grooves or depressions, which was particularly the case in the neighborhood of the suckers; to the naked eye the head of the worm seemed blackish. Previous observations had already drawn attention to the dark color of the head in certain tapeworms, but this was due to a granular pigment deposited in the cellular tissue, and bearing no resemblance to the mercurial deposit mentioned above as being present in the external tegument of the head of the tænia. In the same way it cannot be mistaken for the collections of pigment which Leuckart has noticed in the vagina, since he has himself stated that these collections were found only in old proglottides, while those found in the Gottingen case were situated in young and living proglottides. The remarkable part of this observation is the enormous amount of mercury absorbed by these parasites without having any appreciable influence on their vitality; with the exception of the gray coloration, microscopical examination did not reveal any difference from the parasites found in healthy animals.—*New England Medical Monthly.*

Unhealthy St. Petersburg.—An epidemic of small-pox is supposed to have broken out in St. Petersburg, and the entire population of the capital, of all classes, has been seized with panic. Many thousands of rich and poor daily besiege the authorized vaccinators, who are quite unable to cope with the rush, and the quantity of lymph obtainable at one time is altogether insufficient. General Grösser, the Prefect, issues all manner of sanitary regulations in connection with measures against the disease, and compulsory revaccination has been ordered in all schools and various other large establishments. The doctors declare privately that the matter is not so bad as is generally believed, but that the authorities are only too glad to see the population frightened into measures of precaution and sanitation generally. Considering the permanently insalubrious conditions of St. Petersburg, which have been recently aggravated by frequent inundations, a panic of the present kind is supposed to do more good than all the neglected and mostly impracticable instructions of the police.

A Substitute for Parataloid.—The Paris correspondent of the *Medical Press and Circular* writes that two French physiologists have been trying experiments on rabbits to test the value of goat's blood as a remedy for tuberculosis, and were so pleased with the result that they have just made their first attempt on man. The rabbits were rendered tuberculous by inoculation, and then a small quantity of blood was injected, not transfused, beneath the tissues at intervals. The "bunnies" did not seem much the worse for the operation; on the contrary, those who were thus treated recovered, while the others succumbed to the malady. MM. Picq and Bertin naturally thought that the human species ought to profit by the discovery, and have begun experiments in that direction. A young man who was pining away from the dire disease was chosen for the operation, and submitted to it with a good will deserving of success. Half an ounce of goat's blood was injected into the tissue of the leg, the blood coming in an uninterrupted stream directly from the animal. The patient felt very little uneasiness after it, no swelling occurred, and it was said that both the fever and cough diminished in a few hours. He will receive another injection in a few days. All that can be said of the affair is that MM. Picq and Bertin are very sanguine as to the discovery.

To Remove the Stains of Pyoktanin from the Hands.—The staining of the hands is a disagreeable feature in the use of pyoktanin, but this can be removed, according to *Merck's Bulletin*, by washing with a ten per cent. solution of castile soap in alcohol, the solution of chlorinated soda, or tincture of soap.

rubber sheath. The bifurcated needle is curved so as to include the tonsillar tissue in its grasp. It is made of platinum and is insulated to within a centimetre of the points. The points are separated by pushing the steel shaft through the insulating sheath, and by means of the thumb-screw they are made to approximate each other and thereby caused to pierce the submucous tissue of the tonsil. The needle carries but one current (the negative), which is denutritive and promotes absorption of the fibrous exudation without destroying the mucous membrane. The positive pole is applied by a sponge electrode to the skin external to the affected tonsil. From five to twenty milliampères will be found sufficient, applied at intervals of one week. The operation is very much facilitated by the local application of cocaine.

The Therapeutic Value of Sodium Iodide.—It has been asserted by many that iodide of sodium was an inert substance, or at least that it exerted no medicinal action similar to that of iodide of potassium. Dr. Gingeot, of the Hôpital Saint-Antoine, has made a number of experiments to settle this question, and finds that the drug does possess undoubted therapeutic properties, equal to, if not superior to, those of the potassium salt, in cases of arteriosclerosis, though it may be less potent in cases of syphilitic disease.

NOTES ON THE EFFECT OF THE ANILINE DYES, ESPECIALLY THE BLUE PYOKTANIN, IN THE TREATMENT OF INOPERABLE MALIGNANT GROWTHS.

BY WILLY MEYER, M.D.,

ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS.

AT a time when tuberculin and cantharidate of potash are injected for the cure or the improvement of tuberculous troubles, and our medical journals and periodicals are constantly full of reports which are the result of a comparatively short time of observation of the individual medical man, it seems rather queer to join this interesting and at the same time necessary rapidity of publication with new remedies applied for the cure or improvement of another chronic and malignant disease. If I nevertheless give a preliminary report of an eight weeks' use of the aniline dyes, especially of pyoktanin (blue), in the treatment of inoperable malignant growths, I do so because this my rather short experience with the aniline dyes made me believe that they will most probably play an important rôle in the treatment of such patients as suffer from cancerous (and sarcomatous) new growths, where neither knife nor cautery can bring any more help; and because I think that if many colleagues try the aniline dyes for this unhappily so common disease, important facts in regard to use and effects will be gained so much quicker, mistakes in dose and application found out meanwhile by experience can be avoided, and many poor creatures may perhaps be benefited so much sooner, if only in regard to alleviating the pains which so frequently accompany exulcerated facial neoplasms.

The literature on the effects and on the value of external as well as internal application of the aniline dyes, especially pyoktanin (blue), in general surgery is comparatively small yet. Notes in this respect will be best found in the second treatise of J. Stilling,[1] Professor of Ophthalmology at the University of Strasbourg, Germany, who, together with Dr. Wortmann, made careful bacteriological and chemical researches with the different aniline dyes. He baptized one of the methyl-violets, which showed the greatest antiseptic power, pyoktanin, and introduced two different kinds of the drug, the blue and the yellow (pyoktanin cæruleum and pyoktanin aureum). The latter is also called auramin. Its antiseptic power is far less than that of the former one; it is mostly used in superficial wounds and on the face, as it dyes the tissues yellow.

In regard to this special subject, viz., the use of the aniline dyes, especially pyoktanin,[2] in the treatment of inoperable malignant growths, only a few gentlemen have so far reported. Stilling mentions in his second paper[3] that he succeeded in curing with pyoktanin an extensive exulcerated epithelioma of the face (ulcus rodens) which, beginning in the middle of the dorsum of the nose, involved the entire wall of the lachrymal sac and half of the upper eyelid. He first sterilized the surface with a large pyoktanin stick and then powdered the pure substance on the formed eschar. This procedure was repeated a number of times. A hard cover was thus formed, which could not be pulled off. It came off by itself after a number of weeks, and underneath a smooth cicatrix presented itself. The eyelid, of course, was contracted. He states this case to show how effective the aniline dyes can be even in such cases under special favorable circumstances, and not to claim to have found a remedy for cancer. In another case, which seemed to be much more favorable, this kind of application had no success whatever.

On January 30, 1891, Professor v. Mosetig-Moorhof read a very interesting paper before the Vienna Society of Physicians, "A Contribution to the Treatment of Inoperable Malignant Growths,"[1] in which he reported on his experience with pyoktanin in such cases. He stated that on November 20, 1885, he had presented to the same society two patients with very extensive inoperable epithelioma of face, in which he had succeeded in removing all the diseased tissue with the help of a drug (lactic acid). But as early as 1883 he had treated an inoperable round-cell sarcoma of the right groin of a man, aged fifty, with parenchymatous injections of a one per cent. solution of an aniline dye (anilinum trichloratum). Eight weeks later the œdema of the lower extremity had disappeared, the large tumor was reduced to a nodule of the size of a walnut, and the ulceration had healed. The patient left the hospital cured and attended to his business. He died one year later of pneumonia; the neoplasm had not recurred. As in the course of the treatment he had nearly lost his patient by using one drachm of the one per cent. solution in one sitting, most probably on account of poisonous impurities in the drug,[2] and as he later saw in three other cases, treated in the same way, very annoying and dangerous general effects, he stopped these researches and only started them again after having read Professor Stilling's discovery of pyoktanin, a powerful antiseptic drug, which is perfectly harmless and chemically not poisonous to the organism. In the treatise referred to, a number of cases are reported which demonstrate that in pyoktanin a remedy seems to have been found which can possibly bring help in cases of inoperable malignant growths, where formerly the patient and doctor likewise seemed to be absolutely helpless.

At the same meeting Dr. Neudoerfer reported[3] that in the spring of 1890 a woman, more than seventy years of age, came under his treatment, who suffered from an inoperable cancer of the right breast. The whole breast and surrounding tissues were densely infiltrated by a cancerous growth and partially exulcerated. The ulcerations were first dressed with pyoktanin solution, later on spread with a powder, which consisted of one to two parts pyoktanin to one hundred parts talcum venetum. The patient seemed to be very satisfied with this treatment. She still complained of pain during the night, but the neoplasm, although not diminished in size, stopped growing.

In November, 1890, he treated a second similar case in a woman more than sixty years of age in the same way. In this case also the ulceration did not spread: the infiltrated glands in the axillary cavity became continuously smaller and movable.

[1] Anilin-Farbstoffe als Antiseptica und ihre Anwendung in der Praxis. Zweite Mittheilung. Strassburg. 1890.

[2] In mentioning "pyoktanin" in the following notes always the "blue" one is alluded to.

[3] Loc. cit., p. 96.

[2] These impurities are arsenic, sulphate of copper, and chlorate of zinc.

[3] Wiener klinische Wochenschrift, 1891, No. 6, p. 113.

Stilling[1] proposes to make use of such aniline dyes for parenchymatous injections of inoperable neoplasms, which slowly, and for a small percentage only, dissolve in a 0.6 per cent. solution of chloride of soda—viz., blood. The injected fluid will then not as quickly leave the tissues, into which it has been injected, by diffusion, and therewith enter the blood. In the latter respect he advises great care, as the dye enters the red blood-corpuscles, and, if entering in too large an amount, may endanger their function, possibly destroy life. He believes that ethyl-violet will best answer this purpose. Only 0.7 to 0.8 part are soluble in 1,000 water; it has besides the strongest antiseptic power of all the drugs belonging to this class. Stilling called it ethyl-pyoktanin; it is also manufactured by Merck. In regard to its practical application in inoperable cancer cases, he thinks it best "to make use of the well known method of Von Nussbaum, who tied the arteries which fed the neoplasm. in order to stop its growth. The tissue, thus having been made bloodless first, should then be thoroughly dyed in all its parts, and that as rapidly as possible."

Von Mosetig presented four of his cases, previously referred to, at a recent meeting of the Vienna Society of Physicians[2] (March 13th). The patients had all been materially improved, but were not yet cured. He also stated that a woman with papilloma of the bladder, who had been treated with injections of pyoktanin, 1 to 1,000,[3] had had no more vesical hemorrhage and was able to attend to her work; she had also got rid of the troublesome stranguria. He assumed that the papilloma had materially shrunk. A gentleman with an immense inoperable adeno-sarcoma of the pelvis, which had made him an entire invalid, was so far improved by the color-cure that he again entered society and left for the South. The rest of the tumor presented about the fifth of its original size. Sixteen more cases of this kind were submitted to the same treatment. Fourteen of them were materially improved; two died. In none of the cases did the neoplasm spread during the treatment. One of the deaths was due to a sudden compression of the trachea by a large sarcoma of the thyroid gland; the other was caused by an uncontrollable venous hemorrhage occurring in the course of the treatment, in a man with a sarcoma of two fists' size, which was seated in the parotid region and the right side of the neck. The post-mortem revealed that the superficially ulcerating neoplasm had undergone fatty degeneration in the deeper region, which was attributed by the author to the use of the pyoktanin. The tumor had infiltrated the wall of the internal jugular vein and then, by its breaking down, given free exit to the venous blood. Von Mosetig concludes that we had better be careful with this treatment in cases of malignant growths which have developed in the neighborhood and around large blood-vessels. He is inclined to avoid injection into the tumors which involve large veins and also into those which cannot easily be reached by the needle of the syringe. He now prefers a solution of 1 to 500 as a standard solution, which is filtered through heated asbestos to remove undissolved crystals, which might plug the needle, and makes the injections in a concentric manner, letting his needle enter into the surrounding healthy tissues. Von Mosetig does not share Stilling's fear that too large an amount of the dye could enter the blood and thus do harm by staining the red blood-corpuscles. In several hundreds of these injections neither he nor his assistants had ever seen any untoward accident. Microscopical examination of extirpated pieces of three different new growths, which had been injected, made by Riehl, of Vienna, demonstrated that the nerves, muscles, connective tissues and young epithelial cells were diffusely dyed, but the nuclei only slightly, or not at all. To explain this phenomenon and at the same time the necrobiosis or fatty degeneration and reabsorption of the growths after the injections (which in his opinion can only take place if the cells and the cell-nuclei of the neoplasm themselves have really been affected by the pyoktanin), Von Mosetig advances the hypothesis that the pathological cells or their nuclei contain a specific chemical substance, which is able to reduce the aniline dyes in such a way that the latter lose their blue color; in other words, that this at present unknown substance reduces the blue aniline dyes to white, that is leukaniline. When the tumor has been extirpated and sections have been prepared from it for microscopical examination the leukaniline in them, being exposed to the oxygen of the air, turns blue again. Now a poisonous chemical product has lately been found in carcinomata by Adamkiewicz, which, inoculated in rabbits, kills them by paralysis of the brain in a few hours. Perhaps this poisonous product reduces the aniline dye and therewith becomes neutralized itself. This again might then explain the following regressive fatty metamorphosis and arrest of further growth. It is, however, necessary to state that this poison has only been found in cancers and not in sarcomata, which also react upon the aniline dyes.

Billroth[1] is rather sceptical in regard to the value of pyoktanin injections in cases of malignant growths. Three patients, having far advanced sarcoma (posterior aspect of thigh, sternum, popliteal space) got worse; one of them died of sepsis. The tumors were softened and the covering skin was perforated. This occurrence can only be looked upon, according to Billroth, as unfortunate to the patient. The exulcerated growth troubles the patients much more and will render their condition more dangerous. Patients afflicted with exulcerated cancerous growths also did not improve. Billroth does not believe that pyoktanin, when injected, has any specific influence whatsoever, but that it is merely the water, which, forcibly pressed into the tissues, makes them swell and later unable to live.[2] The researches are continued in his clinic.

The aniline dyes were first externally applied in two of my patients at the Country Branch of the New York Skin and Cancer Hospital. The treatment was started on January 2d, this year.[3] We used fuchsin, first in solution, then in ointment. Since February 20th, after having read Von Mosetig's original communication, I substituted pyoktanin for fuchsin, as it is chemically pure, especially free from arsenic, and also more soluble in water.

Since that time nine patients of the New York Skin and Cancer Hospital, all suffering from cancer, have been treated with local applications of pyoktanin in ointment, powder, or substance, and with parenchymatous injections of pyoktanin solution, 1 to 300. Their cases have been very carefully observed and treated by Dr. F. Torek, Assistant-Surgeon to the Skin and Cancer Hospital, the house-staff of the City Hospital and the Country Branch, and myself. Two patients of my private practice, one of whom has a recurring cancer of the breast, the other an inoperable cancer of the rectum, which necessitated anterior colotomy three months ago, have also been subjected to this treatment (in the first ethyl-pyoktanin was first used). They have been, however, only for a short time under observation. Their histories can therefore not be used for this communication. In two of the nine hospital patients the treatment was begun when both were very

[1] Ueber die Therapeutische, Verwerthung der Anilin-Farbstoffe. Wiener klin. Wochenschr., 1891, No. ii., p. 201.

[2] Wiener klin. Wochenschr., No. 12, p. 224, and Wiener Med. Presse, No. ii., p. 429.

[3] According to my experience with irrigating irritable bladders with pyoktanin solution, 1 to 1,000 was found to be too strong. One should rather begin with 1 to 5,000 or even 10,000, and then slowly increase the percentage.

[1] Wiener klin. Wochenschr., No. 12, p. 236.

[2] Stilling is strongly opposed to this explanation (Wien. klin. Wochenschr., April 2d, p. 263). He maintains that it has been clearly shown "that the living protoplasm of plants, as well as animals, is colored and at last destroyed by the aniline dyes. The latter takes place as soon as the dye is introduced into the cell in so large a quantity that the cell cannot get rid of it any more by diffusion." Stilling advises at the same time to make up the solution with a 0.6 per cent. solution of chloride of soda, in order to avoid embolies of the capillaries with undissolved pyoktanin-crystals (Neudoerfer).

[3] In my first communication to the New York MEDICAL RECORD (March 7, 1891, Correspondence), the date of commencing this treatment was erroneously put as January 6th.

low already. One of them died from cachexia, the other from a chronic nephritis of long standing. I am sure that, in both, the very short use of pyoktanin had nothing to do with their death. I nevertheless regret that a post-mortem could not be made. The other seven are still under treatment, three of them only for a rather short period. Their histories will appear in a later paper.

The histories of the remaining four cases, as far as they may perhaps be of interest, are in a condensed form as follows :

Case I.—Mrs. E. M——, aged seventy-three; German. Large ulcerated epithelioma (rodent ulcer) of scalp, forehead, nose, and eyes of twenty years' standing. Left eye entirely destroyed; also a part of both lids of right eye. Patient is still able to see indistinctly with the latter to a distance of about one to two feet. Excruciating pains, especially during the night, for a long time.

January 2, 1891.—Application of fuchsin, 1 to 250 (equal parts of alcohol and water), on a portion of wound. (Dr. A. C. Lewis.)

January 6th.—No discharge from this spot; surface of a more healthy appearance.

January 10th.—There is a little discharge. The sore presents "a fairly healthy granulating surface."

February 14th.—Condition unchanged; there seems to be no tendency to spread.

February 20th.—Patient states that the former pain has entirely disappeared. "This is the best treatment she has so far undergone." Application of pyoktanin 1 to 200 talcum.

March 24th.—Wound continues to present a more healthy, rather granulating base, and has perceptibly decreased in size around border on top of head; a small area has cicatrized there; at several other points, notably at the middle of the forehead, there is a tendency to heal. The hard borders have softened. Discharge scanty, but not as much as under the original fuchsin treatment. A number of grooves seem to be more excavated than formerly (this is most probably due to necrobiosis of the cancerous tissue). Patient has but little pain. The borders of wound touched with large pyoktanin stick, likewise the right upper eyelid; powder, strengthened to 1 to 50 talcum.

Case II.—G. B——, aged seventy-one; German. Defect of nose, recurrent exulcerated epithelioma of neighboring parts of both cheeks and of glabella, of inner third of the left lower and both right eyelids, cancerous infiltration of the upper lip.[1] Since 1886 rhinoplasty twice performed at the German Hospital; recurrence; amputation of the second nose, which had been made by plasty, in 1889, at the New York Skin and Cancer Hospital. A number of further attempts during this year to check the continuous spread by operative interference, also applications of different chemicals without result.

January 6, 1891.—External application of fuchsin solution, 1 to 200 alcohol, started; on account of pain lanolin was soon substituted for alcohol.

February 25th.—The former frequently excruciating pains, which disturbed the sleep, have entirely disappeared; the secretion has stopped. The base, formerly showing all the characteristics of an exulcerated epithelioma, has become smooth and rather resembling a granulating surface. The grooves are more shallow, the hard and thickened borders nearly all around soft and sunken in. During the seven weeks that the fuchsin has been in use the growth has not spread, except on the left cheek, where a small nodule, still surrounded by healthy tissue, has made its appearance near the border. A perforation through the upper lip into the mouth has also not extended.

March 4th.—The whole surface was painted with the large pyoktanin pencil, and then powdered with pyoktanin in substance. Parenchymatous injections, 15 minims each, of pyoktanin solution, 1 to 300,[2] were made underneath small, hard nodule in left cheek, both sides of upper lip, and into recurring exulcerated cancer of the size of a small cherry in the left submaxillary region (a large secondary growth had been removed there eighteen months ago); injections in the face very painful. In the following days patient complained of a great deal of pain.

March 6th.—Pyoktanin, 1⅔ grain in capsule, administered internally, was not retained by the stomach.

March 11th.—Second injection, 15 minims at different points of upper lip; 8 minims in the submaxillary growth.

March 13th.—Parenchymatous injection of 20 minims into lower half of right border of the ulcer; the border is still swollen.

March 16th.—Patient complains of continued pain. The perforation through the upper lip into the mouth has extended (rapid breaking down of former infiltration). The wound appears to be deeper. The left eye is injected, its lids swollen (paralysis of vasomotor nerves?). Patient states he has by far more pain than under the fuchsin treatment.

March 17th.—Fuchsin ointment reapplied.

March 25th.—Patient complains of no pain. The sore appears rather healthy, but has extended in its lower part, the hard border which was especially injected with the pyoktanin solution having broken down on many spots. Nodule on left cheek and in submaxillary region partially necrosed, giving exit to a very scanty dark-bluish secretion. No œdema. So far no tendency to cicatrization.[3]

Case III.—Mrs. C. M——, aged fifty-nine; German. Recurrent cancer of right breast. Amputatio mammæ and extirpation of cancerous axillary glands at the German Hospital. Double ligature and excision of a piece about one inch long of vena axillaris. Diffuse cancerous infiltration surrounding the subclavian vein and reaching under and above the clavicle had to be left behind. Primary union of the wound. Admission to the Skin and Cancer Hospital, January 9, 1891.

February 20th.—Œdema of right arm, which can only be very little abducted from the chest-wall. Infiltration in right infra-clavicular groove and quite markedly also below the broad scar, which is the result of the operation. Above the latter, especially toward the axillary region, disseminated small cancerous nodules. Injection of 1 drachm of the pyoktanin solution into different spots above the scar. Massage for one-half hour with the intention to press the fluid upward into the axillary cavity. During the following night patient complained of a great deal of pain in axillary region. Temperature normal.

February 23d.—Injection of the same amount; immediate marked bluish discoloration of the skin. It is evident that the small nodules are not injected. Evening temperature, 100.5° F., rectum.

February 26th.—Injection of 1 drachm into the growth, and 15 minims underneath and into a number of cutaneous nodules. Massage.

February 27th.—The mucous membrane of the gums along the border of the teeth appears bluish.

March 3d.—Cicatrix perforated in length of one inch; blue-colored, œdematous tissue making its appearance. Pain on pressure above this spot. The whole infra-clavicular region pinkish-red and œdematous. No rise of temperature. The nodule, injected five days ago, has flattened, and is decidedly indistinct in its contours. Injection of four small cutaneous nodules at their base with 15 minims of the pyoktanin solution each. One more drachm into different spots of the diffused swelling, 2 drachms in all. The newly opened spot is powdered with pyoktanin in substance, and then covered with a piece of iodoform gauze.

[1] Patient was presented to the New York Surgical Society on February 25th, and to the Scientific Society of German Physicians on February 27th. Cf. Report of the New York Surgical Society of February 25th, in New York Medical Journal, April 11th.

[2] Blue stains on the operator's fingers, got in making the injection, will be best removed by using the liquid green soap, or a solution of Castile soap in alcohol, 1 to 10.

[3] At time of correcting proof (April 21st) cicatrization has started at different spots.

March 6th.—One pill of pyoktanin, 1⅔ grain, in capsule, administered internally, was soon rejected. The small nodules have softened and are almost imperceptible to the touch. The infiltrated area also softer and œdematous. Patient can move the right arm much better than before the injections. Wound again dressed with pyoktanin in substance.

March 8th.—Slight hemorrhage from the broken spot.

March 11th.—The infra-clavicular region gives the sense of fluctuation; by pressing upon it a quantity of a thick, dirty bluish fluid, intermingled with shreds of broken-down tissue, and a great deal of fat escapes through the fistulous opening in the cicatrix.[1] Small fluctuating spot at the outer angle of the latter is incised. It contains blood mixed with the same grayish-blue material. Injection of 1 drachm of the pyoktanin solution.

March 13th.—Patient complains of pain in the region of injections. There is a continuous colored discharge from the opening.

March 16th.—The spot immediately above the cicatrix decidedly flattened, up to three fingers' breadth below the lower border of the clavicle. Pain on pressure, fluctuation, continuous discharge. A number of the small nodules, which formerly seemed to have entirely disappeared, again perceptible to the touch. I think that the disappearance was partially an illusion, owing to the occurrence of œdema, which temporarily concealed the nodules, but, which subsiding, left them again distinct. (A few of them certainly were reabsorbed.)

March 17th, 20th, and 24th.—Injection of 1 to 1¼ drachm of the pyoktanin solution each time.

March 26th.—The fistulous tracks in the injected area were split under ether. It was found that a thick ramified mass, dyed deep blue, was lying in the midst of normal uncolored fatty tissue. This mass evidently was necrosed tissue, which could be easily shelled out with the finger or the sharp spoon; in many spots it was still adherent to its surroundings. The underlying muscles and neighboring tissues appeared to be normal in color, but rather indurated. Dr. I. Adler kindly consented to make a microscopical examination of the necrosed mass. The doctor's report reads as follows: The fluid, of pale-violet color and containing small scraps of a solid matter, which formed an uneven and irregular sediment, was submitted to microscopical examination, and showed the following:

1. A colorless, serous, slightly viscid fluid. In this fluid were suspended globules of free fat in great profusion and of all sizes; fat-crystals; innumerable leucocytes of all kinds, principally, however, of the large polynuclear species; a comparatively small number of red blood-corpuscles, all these of natural appearance and entirely unstained. Furthermore, large masses of granular amorphous detritus, either suspended loosely throughout the fluid or else gathered together into more compact masses. These latter were sometimes diffusely stained of a very pale, grayish-violet tint.

2. The solid particles, which consisted of portions of fatty tissue and of patches of epithelial cells. The fatty tissue showed the regular polygonal fat-cells, sometimes emptied of their contents, sometimes filled with them. In either case a distinct and diffuse bright violet-staining of the membrane could be made out, while the fat itself never showed any color. The epithelial cells were of the large, irregular, flat pavement species, either singly or in groups. Wherever an epithelial cell was found, it was at once recognized by its deep saturated stain. The coloring was entirely diffuse, and no nucleus could be made out without the aid of acids.

The wound was loosely packed with iodoform gauze, which was freely dusted with pyoktanin in substance. Pyoktanin gauze, as manufactured by Merck & Co., was not just at hand.

March 30th.—First change of dressing; gauze removed. Very little secretion. Wound in perfect condition.[1]

Case IV.—Mrs. W——, aged forty-six; English. Admission to the City Hospital, February 24, 1891. Large ulcerated inoperable cancer of left breast, which involves both inner quadrants. Disease present for two years. Left breast is about three or four times larger than the right healthy one, and hangs down three inches lower. Nipple retracted and ulcerated. In inner, upper quadrant a large deep ulceration with thick everted borders; in left axilla and in the pectoral region a great number of small, cancerous, cutaneous nodules of various sizes. Superficial cancerous sore in left axilla. No œdema of left arm as yet.

February 28th.—Parenchymatous injection of pyoktanin solution, 1 to 300 (1 drachm), into both lower quadrants under the ulceration. Needle entered at different points and was gradually pushed forward from the healthy surrounding tissues. In the afternoon patient felt chilly and rather uncomfortable, complained of dizziness and a burning sensation over a certain portion of scalp. No rise of temperature. Ulceration powdered with pyoktanin in substance.

March 2d.—General condition good. Discharge of ulcer less offensive. Injection of 2 drachms of pyoktanin solution at different spots.

March 3d.—No dizziness at this time after yesterday's injections. One capsule of pyoktanin, 1⅔ grain, taken internally, thrown up within two hours. At the same time patient's bowels move quite freely.

March 4th.—Evening temperature, 101⅔° F.; no appetite; patient feels uneasy; capsules discontinued.

March 5th.—Three small cutaneous nodules in upper, outer quadrant injected; turned blue soon after; surface, when touched with a needle, was found to be anæsthetic; local anæsthesia confined to the bluish surface only, lasted over half an hour; extirpation of one nodule (for microscopical examination) thirty minutes after injection, was pronounced to be painless. Wound stitched with catgut and painted with pyoktanin collodion, three per cent.; parenchymatous injection into growth, 1 drachm.

March 6th.—Pyoktanin, 1⅔ grain, given internally as before, again badly borne; patient vomits and feels very weak; temperature, 103° F.

March 7th.—The nodules injected two days ago are noticeably smaller and less infiltrated; they were, with a number of others, reinjected, as also was the large tumor. Total amount, 1¼ drachm. A cyst, which had formed under the ulcer, was aspirated; it contained unstained blood.

March 9th.—The small nodules, mentioned before, considerably smaller and softer, but still perceptible. Parenchymatous injection of 1½ drachm into tumor and nodules.

March 11th.—Injected with same amount.

March 12th.—Patient dizzy and faint; no appetite; vomiting.

March 20th.—Tumor much softer, and in both inner quadrants markedly smaller. The often-mentioned hard nodule in inner upper quadrant has softened somewhat, but is still hard at its base. It was injected with 20 minims pyoktanin solution, 1 to 200; the larger growth with 1 drachm of same strength.

March 22d.—Since last injection stomach irritable; food frequently vomited; the skin, especially on the inner side of the tumor, is wrinkled; the formerly raised and everted edges of ulcer have flattened, and are much softer than before; the powdered pyoktanin on the ulcer always forms a dry eschar, which can be removed with the forceps, and is evidently necrosed tissue. On removing the eschar a dyed surface appears, which bleeds slightly; no discharge, but still some smell; below the ulcer two new perforations have formed.

[1] Careful microscopical examination of this fluid was kindly performed by Dr. I. Adler, of this city.

[1] April 21st, when correcting proof: Wound without secretion, closing, cicatrizing. Still some infiltration at inner end of former scar, also near the axillary cavity. Growth checked in its spreading. No parenchymatous injection since March 17th.

March 25th.—Small nodule in the inner upper quadrant has broken down, giving exit to the thick, bluish-dyed fluid; on pressure, a small mass of necrosed bluish tissue appears, and is easily extracted with the forceps. The surrounding shell still hard, but less so than before.[1]

In reviewing these four histories and also considering my experience with pyoktanin as well as ethyl pyoktanin in my private patients, I should like to state the following facts in regard to the treatment of inoperable malignant growths with these aniline dyes, as far as they have been exhibited up to date (April 8th):

The aniline dyes, applied on the surface of exulcerated growths in ointment or powder (about 1 to 200), or in substance, have a strong analgesic effect.[2]

Parenchymatous injections of pyoktanin solution, 1 to 300, repeated every second day till fifth day, the dose not exceeding one and one-half drachm, have in my cases proved to be innocuous to the general system.[3]

The symptoms following the injections are either general or local.

The general symptoms, which can also follow the internal use of methyl blue (as recommended for inoperable malignant neoplasms by Dr. Max Einhorn of this city),[4] are nausea or vomiting, weak and slow pulse, headaches, general malaise. These symptoms may come on the same day or the day following the injection; as a rule, they do not come at all; now and then there is a slight rise of temperature, usually subsiding within twenty-four to forty-eight hours.

The local symptoms are:

1. Pain following the injection. It may be of long or short duration, slight or severe. It is more severe where the cancerous infiltration affected by the injection is dense (epithelioma of face, disseminated cancer of breast, etc.). It seems that local anæsthesia may follow the injection.

2. Œdema, coming on either acutely, and then accompanied with slight redness (non-inflammatory) and pain on pressure, or rather in a subacute form. This serous transudation of the growth may be the first step to reabsorption. The slight fever, observed in a number of patients, soon following the injection, had then to be looked at as being an aseptic one, possibly due to this reabsorption.

3. Breaking down of the injected tissue, with perforation of the skin or scar, which latter is the result of the operation (aseptic necrosis). By using a stronger solution, 1 to 200, the necrobiosis seems to be more rapid in smaller nodules. How far the surrounding infiltrated shell which is left behind is apt to spread farther can only be determined by continuous observation. It may be advisable to use a weaker solution, 1 to 500, instead of 1 to 300, as we can thus dye a larger portion of the growth in one sitting, without increasing the dose of pyoktanin. We then inject a larger quantity of solution and still need not apprehend general symptoms. Perhaps the weaker solution will not destroy the tissue so rapidly and thus rather induce reabsorption than necrosis. The sinus or sinuses established by the breaking down of the tissues give exit to a thick, dark-blue fluid, which, by microscopical examination, proves to be not colored pus, but débris of the injected neoplasm. It is generally intermingled with shreds of necrosed tissue. In splitting these sinuses one may find necrosed, deeply dyed, ramified tissue, surrounded by normal undyed fat and muscles,[1] which is easily shelled out. Whether it will be necessary and possible to remove the necrosed tissue by operation or whether this tissue will be extruded by means of a slow disintegration and longer secretion cannot yet be determined. We also have to prove yet, whether operative interference in this stage will really benefit our patients. Perhaps nature gets slowly rid of the necrosed tissue without help. As it seems, the carcinoma tends more to necrobiosis and perforation during this treatment than the sarcoma. I personally could so far only subject cancer cases to the color cure. (V. Mosetig had his most striking results in patients suffering from sarcoma (see above). He maintains that the injections, made under antiseptic precautions into neoplasms, which are still covered by healthy skin, produce necrobiosis and fatty degeneration, which is not followed by perforation, but by reabsorption.[2] Billroth, on the other hand, saw rapid softening and perforation in two out of three patients who suffered from sarcoma and were treated with the injections.)[3]

4. Breaking down of the injected tissue (necrobiosis) with subsequent reabsorption (Cf. 3). This will probably be oftener seen, if we stop the injections for some time as soon as spots in the growth have softened, and only start them again after these spots have shrunk (provided, of course, that they did not perforate). Small, hard nodules in the skin, as seen especially in the disseminated cancer (recurring cancer of breast), can entirely disappear in a very few days, even if the pyoktanin solution was injected into their base.[4] Perhaps the rapid disappearance is not reabsorption but only an illusion, which is caused by the œdema of the immediate surrounding tissue. A number of the nodules reappear after a few weeks, sometimes rather multiplied. The attempt at dyeing these small nodules directly, by pushing the needle right into them, is frequently unsuccessful, even in regard to the microscopical appearance, and causes severe pain.[5]

An infiltration of hitherto healthy tissue with the neoplasm, in consequence of this treatment, has not been observed in a single case.

In no case did the growth spread during the treatment.

Applications of pyoktanin in substance on exulcerated tumors slowly removes the diseased tissue in the shape of dry gangrene. There is no suppuration under the eschar, on account of the strong antiseptic qualities of the dye, and consequently no cachexia. Pyoktanin is, however, no deodorizer. It also is no stypticum.

It may be advisable to combine the parenchymatous injections and local application of pyoktanin with giving aniline dyes internally. Pyoktanin is, in my cases at least, not borne by the stomach. Methyl-blue seems at present to be the most preferable.

If it could be proved by further observations that continued injections determine the necrobiosis of "all" the diseased tissue, the use of the aniline dyes, especially pyoktanin in its different ways of application and methyl-blue, will have a permanent place in operative surgery, no matter how much time the cure demands, no matter whether it is accompanied by pain, inconvenience, and dangers to the patient.[6]

[1] April 21st: The last mentioned spot nearly closed; no infiltrated shell. Whole growth greatly reduced in size (1/4 to 1/5); no spread.

[2] I have seen the same effect in other painful sores, as ulcer of leg and especially in fissura ani.

[3] The injections have to be made under careful antiseptic precautions. The needle must be boiled before use and then kept in alcohol. The skin of the area where the injection is going to be made must be cleansed with ether. The solution must be kept in a dark bottle, otherwise it is decomposed; 0.6 per cent. solution of chloride of soda should be used instead of water.

[4] Methyl-blue was first used internally by Ehrlich (Ueber schmerzstillende Wirkung des Methylen-blau, Deutsche Med. Wochenschr., 1880, No. 23). Lang saw good effect of its internal administration in cases of cystitis and pyelitis (Wiener klin. Wochenschr., 1891, No. 6, p. 114). Methodical internal application of methyl-blue as a help in hopeless cancer cases was first tried and recommended by Drs. J. Rudisch and M. Einhorn, of this city (New York MEDICAL RECORD, March 21, 1891, Correspondence). The proper maximum dose pro die seems to be about five grains. It is best given in capsules, each containing 1 1/3 gr.

[1] This observation coincides with the remark of Stilling, that a normal, living cell will retain the fluid only for a short while (it is well known that the fat-cells are never stained by aniline) getting rid of it by rapid diffusion. Only diseased or dead cells will retain the dye permanently.

[2] Wiener klin. Wochenschr., 1891, No. 12, p. 224. [3] Ibid., p. 236.

[4] Conter v. Mosetig, Wiener klin. Wochenschr., 1891, No. 6, p. 102.

[5] Microscopical examination found the cells and nuclei of the new growth, small or large, unstained (Riehl). To explain this v. Mosetig advanced a special and interesting hypothesis (see above). It must, however, be stated in regard to the examination made by Riehl, that the neoplasm from which the specimen was taken had been injected only once. Perhaps another result had been obtained, were the injections repeatedly made into the same spot before extirpation.

[6] Proper care can do away with or avoid a great deal of the latter. The pains after injections into densely infiltrated spots may, I hope,

It might then be advisable in patients who can still stand some loss of blood to remove as much of the new growth as can be reached with the knife or cautery, and then to inject. The size of the consequent granulating surface, as long as it is only healthy, would be immaterial. Skin-grafting would determine cicatrization.

If, on the other hand, continuous observations should demonstrate that necrobiosis with perforation or with fatty degeneration and reabsorption does only affect a portion of the neoplasm, and diseased tissue is left behind in spite of a long and careful treatment, we will certainly do much better not to begin any such treatment at all, at least not as long as the tumor is still covered by healthy skin. Billroth [1] has already emphasized this fact.

But suppose, that future observations should really demonstrate that the aniline dyes do not specifically attack carcinoma and sarcoma, as Billroth seems to apprehend, their administration will nevertheless be of great value to the poor hopeless patients. We will be able, by using them, to check the "exulcerated" growth from further spreading and thus lengthen life for some time at least; we will prevent cachexia; we will alleviate the sometimes so excruciating pains in such cases of ulcerating neoplasms where neither morphine nor cocaine can bring any benefit.

REMOVAL OF LARGE FRAGMENT OF GLASS FROM LARYNX AFTER LODGEMENT FOR TWENTY-ONE MONTHS.[2]

By CHARLES C. RANSOM, M.D,

CLINICAL ASSISTANT IN DEPARTMENT OF DERMATOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

On July 31, 1890, Mrs. P——, of Troy, N. Y., applied to me for treatment in the inhalation department of the bathing establishment at Richfield Springs, for a throat trouble from which she had suffered for over a year and a half, and gave the following history:

On October 25, 1888, while at lunch with her family, being at that time in usual good health, she was in the act of eating a piece of squash pie, and while doing so suddenly strangled, and for the next thirty minutes it seemed doubtful if she could survive the terrible fit of coughing. The family physician was summoned, and apprised of the apparent cause of such strangulation. Within twenty minutes the physician arrived, bringing with him the necessary instruments for examining the throat and for the removal therefrom of any foreign substance which might cause strangulation.

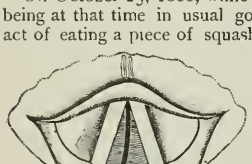

FIG. 1.—The dark line represents position of the glass as it appeared in the mirror.

The physician examined the throat, and after the examination declared that he could not discover any article of food or other body which might have brought on such an attack.

Although nearly exhausted by the struggle, the patient still insisted that there yet remained some obstruction in her throat, which not only choked her, but greatly impaired her power of speech. But her physician was convinced that if anything had lodged in her throat causing the distress which she had explained, it no longer remained there, and had probably been swallowed. However, the patient remained very weak and nearly speechless. For six weeks she was under constant medical treatment. After that lapse of time she began to regain her strength slowly, but for a period of six months she was confined to her house, unable to carry on any conversation above a whisper. She still continued to feel constant irritation, causing her to cough and occasionally to raise phlegm. With slight improvement in her voice and general health, weeks and months passed, bringing with them no permanent relief.

This condition of affairs continued until July 31, 1890, when she presented herself to me for treatment. Upon examination of the larynx I saw what first appeared to be a crack in my laryngoscopic mirror, extending across its face. Upon removing the mirror I found it intact, and then knew that I had a foreign body of some sort to deal with. Upon further examination I discovered that the black line, which I had first thought to be a crack in the mirror, was the smooth polished edge of a piece of glass which hung suspended antero-posteriorly between the vocal cords and on a plane slightly above them, the body of the glass swinging free in the glottis. Upon my making known the nature of the trouble the patient was immediately thrown into such a nervous state that an operation, or further examination even, would not be listened to.

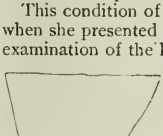

FIG. 2.—Glass after removal. Actual size.

Two days later, on August 2d, the patient returned to me for the removal of the glass. After brushing the larynx with a four per cent. solution of cocaine, I succeeded in removing the glass with the Shrötter tube-forceps, in the presence of Dr. William Baker Crain, of Richfield Springs, and the members of her family. The piece of glass removed, which I take great pleasure in showing you, is doubtless a piece of a very thin wine-glass, which had gotten by accident into the food, and which is triangular in shape, and measures on the three edges, $\frac{7}{8}$ of an inch, 1 inch, and $1\frac{1}{4}$ inch, respectively. Upon removal of the glass, the voice was improved at once, and the irritation which troubled her for so many months, to a very great extent disappeared. After its removal there was seen slight swelling at the posterior point of contact, with a small papillomatous growth. In other respects the larynx appeared quite normal.

The remarkable features of the case are the large size of the foreign body and its character, the length of time it remained in place (one year, nine months, and ten days), and slight results produced from the long continued irritation.

56 WEST FORTY-NINTH STREET.

TWO INTERESTING EYE CASES.

By J. M. BANISTER, A.B., M.D.,

CAPTAIN MEDICAL DEPARTMENT, U. S. A.

CASE I. *Melanotic Sarcoma of the Choroia.*—The relative infrequency of choroidal tumors, which are found in the small proportion of one in every fifteen hundred eye cases, and the pathological interest connected with a case of melanotic sarcoma recently under my care induce me to bring the case in question to the notice of the profession.

Mr. M——, sixty-one years of age, consulted me June 25, 1890, on account of a large growth involving the left eyeball, both lids, and the orbital contents of the affected side.

Upon examination, I discovered a dark colored, somewhat lobulated tumor, about as large as a small orange, protruding from the left orbit, and overlapping the greater portion of the orbital margin. This growth had taken the place of the eyeball, and protruded from between the lids, which, though occupying their relative positions, were

be overcome by paying special attention that the dye is properly distributed through the growth. A larger amount of fluid deposited in one spot must of course greatly increase the local intra-parenchymatous pressure and immediate pains. It will also produce rapid local necrobiosis. The addition of a few drops of a five per cent. solution of cocaine to the fluid, where it is to be injected into infiltrated spots, did also help to reduce the pain. By keeping one's self with the amount inside of proper limits ($\frac{1}{2}$ grain) no poisonous effect need be feared from the use of this salt. A careful antiseptic management of the case will fight all dangers possibly arising from the presence of an open wound.

[1] Loc. cit.

[2] Read before the Laryngological Section, Academy of Medicine, March 24, 1891, and specimens shown

greatly stretched, being spread out, so to speak, over the contiguous portions of the tumor. The lower lid, throughout its entire extent, was firmly adherent to the growth, and had to all appearances become a part of the latter, while the upper lid was free at its ciliary margin, but attached to the tumor near its orbital margin, its base being evidently infiltrated with neoplastic elements. Both lids, notwithstanding their great elongation, were thickened, and of a dusky appearance.

The following history was elicited from the patient and Dr. Banta, Physician of the Mescalero Agency, New Mexico, who had been in charge of the case, and who now accompanied Mr. M——.

Twelve years before, the patient had a very severe inflamatory disease of the eye; the globe became very hard and much swollen, and finally ruptured. Before the rupture the pain had been intense, but after this occurrence it soon ceased. The globe then began to shrink and finally became atrophied, and remained in this condition for *eleven years*.

About one year before the case came under my observation, the eye, which had remained quiescent for so long, became irritable again, and soon thereafter began to enlarge. The enlargement increased very rapidly, and the Agency physician, who had charge of the case, soon discovered a staphylomatous protrusion at the lower portion of the sclero-corneal junction. The tumor escaped from its intra-ocular limits at this point, and soon began to protrude in front of the globe. Its growth now became very rapid, and, when I first saw the case, had attained the dimensions before described. A few weeks before this time the patient had been much weakened by a severe hemorrhage from the growth, which was checked with great difficulty.

I diagnosed the tumor as a case of melanotic sarcoma of the choroid. When the nature of such an affection was explained to the patient, he at once demanded an operation, and persisted in his demands even after having been made to understand the danger of operative measures upon the tumor at this stage of its development (extra-ocular stage) and the almost absolute certainty of the return of the growth in some other organ, or *in loco*, even after a seemingly successful operation.

Under the circumstances, I agreed to operate, and upon June 28th the patient was etherized, and the operation performed with the usual antiseptic precautions. The outer canthus was first divided, and the upper lid separated from the tumor; a narrow scalpel was then introduced into the orbit and the growth encircled by an incision close to the orbital wall, the lower lid being treated as a part of the morbid growth, and, hence, divided close up to its orbital margin. After this preliminary incision, the remaining dissection was performed with scissors curved on the flat, and all of the orbital contents were removed as completely as possible down to the apex of the orbit. The hemorrhage during this operation was fearful, the blood pouring out of the orbit in streams. After the tumor had been removed, the hemorrhage was easily checked. The patient's condition had become so alarming by this time that the removal of the upper lid was postponed until two or three days after the operation, when it was removed close up to its orbital attachment.

During the removal of the tumor its true melanotic character became very evident; it was a typical melanotic sarcoma. All of the contents of the orbit were involved, the sarcoma filling the cavity from wall to wall and from base to apex, and having seemingly taken the place of everything else. Anatomical distinctions were obliterated, the orbit seeming to contain sarcoma, and nothing but sarcoma.

The orbital cavity was treated in the manner usually adopted in such cases, and hence no description of after treatment is necessary.

Some authors advise the application of chloride of zinc paste to the orbital walls, after having carefully removed all visible particles of the morbid growth, in order to cause exfoliation of any diseased bone that may possibly exist, as well as to destroy any remains of the neoplasm which may have escaped observation. This treatment, however, is not free from risk, as one can well understand when he bears in mind the extreme thinness of the roof of the orbit, and the danger of the application of the caustic being followed by fatal meningitis. No one can be sure in such cases that the caustic action will not extend more deeply than desired.

Dr. Noyes states in his recent valuable work on the eye, that in one case in which, after an operation of this kind, he used the thermo-cautery simply for the purpose of checking hemorrhage, fatal meningitis resulted.[1] If such an easily managed instrument in such skilful hands can be followed by this deplorable result, great caution should be exercised in the use of such an uncertain caustic as chloride of zinc.

An immediate result of the extirpation, above described, was total loss of sensation over the corresponding half of the scalp from the orbital margin as far back as the occiput. This was evidently due to the destruction of the orbital portion of the frontal branch of the ophthalmic division of the fifth nerve.

The patient was able to return to his home on July 6th, eight days after the operation. I have just recently received a message from him to the effect that he was never in better health than now, and that he has had no trouble since the operation.

Pathological Considerations.—The original trouble in this eye, which occurred twelve years prior to the operation, was, in my opinion, an irido-choroiditis, which assumed a purulent type, or, in short, became a suppurative panophthalmitis. The eye ruptured, and atrophy of the globe followed. Now this interesting question presents itself: Was the original inflammatory trouble caused by the commencing sarcoma, or was the tumor the result of the former? I believe that the sarcoma was the result, and not the cause. If the neoplasm had been the cause of the inflammatory disease, it would have given unmistakable evidence of its presence in other ways, and would not have remained quiescent for eleven years. This fact, alone, proves it to have been a secondary affection. Soelberg-Wells says: "The causes of intra-ocular sarcoma are yet uncertain, but there is no doubt that it not unfrequently becomes developed after injuries of the eye. It may also be formed in eyes which have undergone atrophy after irido choroiditis, etc. Here, however, we must be on our guard not to mistake cause and effect. But if the eye has been for many years lost from irido-choroiditis, before the symptoms of an intra-ocular growth reveal themselves, it may, I think, be fairly assumed that the latter is a secondary affection. Thus, Mr. Bowman removed an eye affected with melanotic sarcoma, which had been lost from acute inflammation twenty years previously."[2] I feel compelled to make the above long quotation, as it fully sustains my position.

As before stated, choroidal tumors are rare, occurring once in fifteen hundred eye cases; about eighty per cent of these tumors are sarcomata, the melanotic variety being largely in the majority. Of 259 cases of sarcoma of the eye, collected by Fuchs from the practice of different surgeons, 221 occurred in the choroid, and of this number 196 were melanotic.[3]

Prognosis.—I think it highly probable that there will be a return of the sarcoma within a year, either as a recurrence in loco or in some other organ by metastasis. According to Fuch's statistics, out of 117 cases in which extirpation was practised after the tumor had become extra-ocular, there was a local recurrence in 26 cases.[4] Berry says, also, "There are no statistics, as far as I am aware, which give any idea as to the frequency of metastasis; on the other hand, the proportion of cases where complete

recovery has followed the operation, and where the patient has been known to be alive five years afterward, is certainly very small."

At the time of the present writing, my patient seems, from his own account, to be in excellent health, and this fact justifies, in my mind, the operation.

Case II. *A Case of Double Rupture of the Choroid below the Optic Papilla.*—Ruptures of the choroid being of especial interest to ophthalmologists on account of their rarity as well as by reason of the permanently defective vision usually resulting therefrom, I feel constrained to report a case of this character, in which there was a dual lesion in an unusual situation.

Private O— — of the Sixth United States Cavalry, Fort Stanton, New Mexico, was accidentally struck on the right eyeball by a small pebble thrown by a companion early in July, 1890. The pebble coming from the right, struck the globe, between the open lids, on its right or outer side near the equator, the eye being turned to the left at the time. Some weeks after the reception of the injury this soldier reported to me in consequence of defective vision in the eye mentioned.

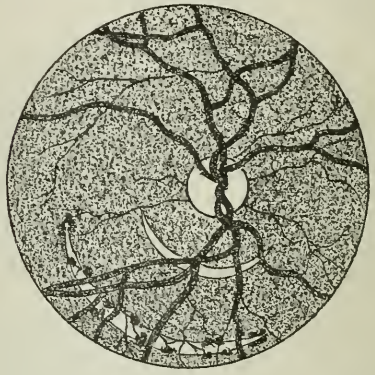
Externally, the eyeball appeared normal, with the exception of the pupil, which was considerably dilated. Upon using the ophthalmoscope, I discovered a double rupture of the choroid, both tears (crescentic in shape, with the concavity of each turned toward the optic papilla) being situated below the disk, instead of on its outer side, as is the almost invariable rule in such cases. The smaller rupture was distant from the papilla about one diameter of the latter, and presented the somewhat yellowish appearance shown in the accompanying figure, its outer extremity bearing the relation to the external inferior quadrant of the optic disk as there depicted. The larger tear was of a decidedly crescentic shape, and was situated near the visible limit of the periphery of the fundus, curving concentrically with its smaller fellow.

I made, from time to time, repeated ophthalmoscopic examinations of this case, and the accompanying sketch is intended to represent the appearance of the fundus at the time of my last examination, about three months after the reception of the injury. This sketch was made from memory, but it serves to give an idea of the relative situations and appearances of the lacerations. The smaller rupture (see figure) was evidently partial, that is, it did not involve all the layers of the choroid, as is proved by its yellowish appearance. If it had extended down to the sclerotic it would have had a decidedly white appearance, such as is exhibited by the larger tear. The latter presented, when last seen, an appearance very similar to that portrayed in the figure. Little islands of pigment were scattered at odd intervals along its sides and around its cornua, and a few were discovered on its surface. Here and there, in the deeper portions of the rent, remains of choroidal vessels could be distinguished (see figure). This rupture extended deeply, as was proved by the glistening, white appearance of the underlying sclerotic. The retina was, to all appearances, unaffected, and the retinal blood-vessels were clearly exhibited as they crossed the rents.

The pupil was still dilated, this being due, most probably, to an involvement of the short ciliary nerves with a resulting partial paralysis of the sphincter pupillæ. Stellwag is of the opinion that this is the cause of the dilatation and sluggishness of the pupil observed in such cases.[1]

Bearing in mind the origin, course, distribution, and function of the short ciliary nerves, one can well understand how such could be the result of a deep choroidal laceration. These nerves, ten or twelve delicate filaments in number, arising from the anterior portion of the ophthalmic ganglion in two separate bundles, pass forward to the globe above and below the optic nerve respectively, and, piercing the back of the eyeball, run forward along the inner surface of the sclerotic to the iris and ciliary body. These nerves supply the sphincter pupillæ, being in fact motor nerves, and derive their motor influence from the third nerve through the ophthalmic ganglion. A deep tear of the choroid, extending well down to the sclerotic, might directly involve several of these filaments, the immediate effect of the injury being either a rupture or a stretching of the filaments directly beneath the rent, with the abolition of their functional activity. Moreover, the remaining ciliary fibres, not directly involved by the tear, might be stretched by the pressing in of the region of the optic papilla as the direct result of the blow upon the globe, as explained in the latter part of this article under the discussion of the mechanism of choroidal ruptures.

This dilatation is not often due to loss of light perception. In my case, while central vision was reduced to $\frac{1}{20}$, light perception was good, the patient even complaining of the sensation of dazzling when exposed to a



bright light; the inconvenience resulting from such exposure necessitated, at times, the wearing of smoked glasses.

As mentioned above, at the time of my last examination, vision was reduced to $\frac{1}{20}$, the patient being unable to distinguish the large E of Snellen at a greater distance than ten feet ($V = \frac{10}{200} = \frac{1}{20}$).

The usual location of choroidal ruptures is in the region of the macula lutea, and the tears run through this region in a vertical direction.[1] Stellwag says that they are almost invariably situated "on the outer side of the optic papilla."[2] In my case, the ruptures were below the optic papilla, and ran somewhat horizontally, and this fact (together with the dual lesion) marks the case as very unusual, to say the least. While a number of cases of double rupture of the choroid have been reported, nevertheless, their rarity is such that they are of unusual interest to ophthalmologists, and it does not fall to the lot of one observer to see many of them. George A. Berry, the celebrated Edinburgh ophthalmologist, says in his recent work on the eye that he has seen one such case.[3]

The mechanism of choroidal ruptures is a very interesting subject, and is one also upon which there is far from being a consensus of opinion on the part of our best authorities. It has been found a very difficult matter to explain satisfactorily why a direct injury to the eyeball will, in the immense majority of cases where laceration results, cause a rupture of the choroid alone, the retina being left intact, and why such tears will almost always be crescentic in shape and arranged "concentrically with the papilla."

Some authorities consider such lacerations due to contre-coup, while others attempt to explain them by stating that, in consequence of the firm attachment of the

choroid at the posterior pole of the eye, it cannot yield readily, as can the retina, when occasion demands. Hence, when a blow is received upon the globe, the retina yields and escapes injury, while the choroid receives the brunt of the injury and gives way. Neither of these explanations accounts for the peculiar shape and arrangement of the lacerations. Becker's theory, as given by Berry, seems by far the most probable. "Becker supposes that at the time of the blow the nature of the distortion which the eye suffers is a pressing in of the optic nerve toward the middle of the eye, producing a fold or a series of folds in the coats immediately surrounding the papilla. At these folds both retina and choroid are stretched, but the former being more elastic and less firmly fixed, yields, whereas the latter, from the nature of its attachments, gives way." [1]

Fort Stanton, N. M., December 26, 1890.

DIABETES MELLITUS.[2]

By JOSEPH T. SMITH, M.D.,

visiting physician to bay view asylum, baltimore, md.

Dr. Peter Shaw, in his "New Practice of Physic," published in 1753, covers the whole subject of diabetes as follows:

"1. A diabetes is a frequent and copious discharge by urine, wasting away the body by degrees.

"2. It may proceed from the serum being too much attenuated; from the glandulæ renales being too much dilated; and from the cuticular vessels being too much contracted.

"3. The signs of it are an immense thirst, not satisfied by drinking, because of the sudden separation made by the kidneys; the whole body is emaciated; and generally a hectic fever, with a quick and weak pulse, accompanies this distemper.

"4. A diabetes is always difficult to cure, and generally proves mortal if it continues long. In old age it is very dangerous, as also when it happens after immoderate venery or fevers of a long continuance.

"5. A subastringent and acid diet is thought proper in this case. Red wine is allowable in moderation. Coffee seems to be no improper liquor; but the decoctum album and tinct. rosar. rub. are excellent, and ought to be drank pretty freely. Moderate exercise is of service if the strength of the patient will allow of it.

"6. As we can have no certain criterion when this distemper is occasioned by the juices being too much attenuated, or the pores of the glandulæ renales too much dilated; the best method we can take is to prescribe such medicines as will equally serve in both cases, and those must consist of astringents, anodynes, and balsamics or agglutinants; which will not only serve to thicken the juices, but also constringe the pores.

"In this case there seems to be no occasion for evacuations, unless when the disorder proceeds from an obstructed perspiration, or when we are sure the fault is entirely owing to the dilatation of the pores, and then the cold bath would be of great service."

Contrast this account with that given by Flint, Loomis, and Roberts, in the latest edition of their works, and you are struck with the great advances which have been made in our knowledge of, and power over, this disease, and it is not unreasonable to suppose that, after another like period of time, we may be able to put it on the list of curable diseases. Dr. Loomis ascribes the delay at the present day to the physiologist when he says, "Until physiology can speak with more definiteness than to say that sugar is disposed of in the system 'either by oxidation, or, as seems more probable, in other ways,' it is useless to speculate as to what organ or functions are at fault."

We all need to work harder and better; but doubtless when we know with certainty all about sugar and its antecedents in the normal body, we shall be able more fully to master its death-dealing influence in the diseased body.

Two things have induced me to bring the subject of diabetes mellitus to your attention once again and arouse an interest in it: the fact that the death-rate is increasing in our city, and the further fact that the subject is of much interest to the profession of to-day, as the space given to it in our journals proves.

Dr. B. W. Richardson says it is "a disease in which there is excessive discharge of fluid from the kidneys, and in which glucose or grape sugar is produced in the body in large quantity, and to which the profuse elimination is due. It is primarily due to changes commencing in the nervous system."

Glycosuria, glucosuria, mellituria, or glycohæmia, as the disease is variously called, though care is needed to give each word its exact meaning, is a disease of no particular climate, and the seasons set no limits to its prevalence, if we except a slight increase in the colder months. In this city, during the ten years from 1880 to 1889 inclusive, the records show that 114 persons died of diabetes, an average of over ten a year. With some variations there has been a steady and rather rapid increase in the death-rate. Thus in 1880 the death-roll numbered 6; in 1888 it was 20; to be followed by a fall to 13 in 1889; and a rise to 18 up to November, 1890. The two winter months, January and December, show the highest death-rate, being 16 and 14 respectively. During the ten years no month was without its death report, the largest being in January—16; the smallest in November—3. This is scarcely what we would expect to find, as the exhaustion and the generally relaxed tone of the system seem to indicate as large, if not larger, mortality in the summer months. What is true of Baltimore is true elsewhere. Dr. B. W. Richardson says of London that there is no time or season of maximum or minimum mortality. It is to be wondered at that a disease which presents so few well marked and always-present diagnostic signs should elude thus far all our efforts to get at its cause. Age, sex, heredity, phthisis, gout, epilepsy, etc., have been assigned a place as predisposing causes, but the extent of their influence has not been determined. The exciting causes range themselves into two classes, those which affect the system generally, as wet, cold, excessive use of saccharine and starchy food, abuse of alcohol, etc., and those which primarily affect the nervous system, as mental emotions, direct injuries, organic lesions, or diseases such as epilepsy, of whose pathology we have no certain knowledge. But whether the cause be one clearly made out, or we can assign no one thing as the influential element, we know that sugar is the offending product, and if we can only find out from what source the abnormal supply comes, we will have gained a great vantage-ground. That the liver is the offending organ there seems but little room to doubt; but it is when we come to ask how, that theory and experiment must come in with their, as yet, unsatisfactory answers.

Dr. Pavy, in his address before the Berlin Congress of this year, says: "I would therefore say that we have here to deal with a failure of power—assimilative or whatever else it may be called—to arrest the passage of carbohydrates through the liver." Two opinions have and still do prevail; Dr. Pavy, in the address just noted, says: "Two points of view present themselves for consideration. We start with the fact that sugar is present in the blood to an extent that is unnatural. Is this due to sugar reaching the general circulation in a manner that it ought not? Or is it to be regarded as natural that all sugar eliminated in diabetes should reach the general circulation, the error consisting of its not undergoing subsequent destruction, thus leading to accumulation." In other words, we find two opinions still held, the one that sugar is manufactured in the liver and poured into the circulation, the other that it is not. Dr. Pavy and those who follow him

[1] Berry: Diseases of the Eye, pp. 175, 176.

[2] Read before the Clinical Society of Baltimore, Md., November 21, 1890.

believe that "instead of the liver being essentially a sugar-forming it is a sugar-assimilating organ. Its great function in relation to sugar is to prevent this principle reaching the circulation to any material extent," and all that we find in the clinical and physiological aspects of the disease can be made to conform to this idea. We have the two substances, liver dextrine and a blood ferment, kept apart by the activity of the liver-cells, and a normal blood-supply going to the organ increases these elements by feeding, or a hyperæmic condition of the circulation in and about the cells, and sugar is the result, or through their nervous supply interfere with the activity of the liver cells, so that the proper balance between the dextrine and ferment is destroyed, and sugar will result, which, when it reaches three per cent., will show itself in the urine.

We have, again, those who believe the duty of the liver to be primarily sugar-making, and the sugar thus made is gradually poured into the circulation, to be in turn broken up into alcohol and carbonic acid for heat-generating purposes, the sugar being only a necessary step in the production of heat, and is to be destroyed as rapidly as formed. Those who hold to this belief have strong grounds for their faith in that the temperature not only does not rise, but actually falls, in this disease, as low, according to Professor Flint, as 95° F.; this one element in heat production being at fault, the temperature falls. Whether a diminution in the excretion of carbonic acid is to be found also we cannot say, as we do not know of any experiments in that direction. The normal production of sugar may be increased by over-activity of the liver cells, the blood ferment may be deficient in quantity or quality, or from obstruction to the circulation; from whatever cause the blood ferment is diminished in quantity. Dr. Mahé says: "The quantity of animal heat depends upon the amount of glycogen poured into the circulation by the liver through the hepatic vein, and its perfect or imperfect consumption in the system. The quantity of glycogen produced by a healthy liver is dependent upon two things: 1, Upon the amount of blood forced through the liver; and 2, upon the degree of activity of its glycogenic-forming cells. All know that interference with certain portions of the nervous mass, the floor of the fourth ventricle, etc., by injury or otherwise, will result in the production of saccharine urine in this case as in the other. That the right pneumogastric nerve is the one involved is supported by the fact that injury to its centre produces sugar in the urine, and that diabetes, many times in its progress, shows affections of those parts supplied by this nerve or its branches, as the involvement of the lungs, stomach, intestines, the slowing of the heart's beat, and the atrophic condition of the pancreas found after death.

This and other facts have led many to look upon this as a nervous disease in its origin, and that it should be classified as such. This hasty review of what may explain for us the cause of diabetes would not be complete without a quotation from Dr. Saundby's exhaustive Bradshaw Lecture on the "Morbid Anatomy of Diabetes." His concluding remarks are: "It is very plain that diabetes, far from having no morbid anatomy, has one of a very complicated kind, and one that cannot be without bearing upon its pathology. The most important lesion is, in my opinion, the wasting of the pancreas, but it is not until this organ has been carefully examined in a larger series of cases than I have been able to collect that we shall be in a position to speak definitely as to its pathological position and value. Of great importance, too, are the changes in the abdominal sympathetic ganglia, though they are too inconstant to form the basis of a satisfactory theory. The liver changes are probably altogether secondary to a functional hyperæmia induced under nervous influence. The other changes in kidneys, lungs, heart, and brain are merely the results of defective nutrition and of long-standing hyperglycohæmia. But the morbid anatomy of diabetes is not yet completed, as is shown by our imperfect knowledge of the state of the pancreas."

Upon a review, hasty as this has been, it is evident that we cannot look upon this disease as dependent upon any single cause; several factors may be concerned in keeping sugar out of the blood, so that when in the future we desire to cure this disease we shall have to carefully see what factor or factors are at fault and treat the disease accordingly. We shall look upon the presence of sugar only as a symptom; just as now no one pretends to treat paralysis without a most thorough investigation into the many causes which give rise to this one symptom. To-day we have no treatment scientifically worth the name. Dr. Pavy says: "Observation shows that the amount of error as regards sugar in the blood, and following upon this sugar to be discharged with the urine, is in proportion to the amount of carbohydrate principles of whatever kind ingested. . . . The first consideration therefore in the treatment is to control by dietetic measures the passage of sugar through the system. The real point, however, to be aimed at, is to restore the assimilative power over the carbohydrate elements of food; and until this has been accomplished it cannot be said that a cure has been effected."

Even dieting needs great care and attention that the nutrition of the individual be kept to the highest possible degree of perfection, and a frequent examination of the urine should be made, and the patient allowed starch or sugar as rapidly and in as large amount as the system will bear—the amount of sugar in the urine being our guide.

We have followed the rule laid down by Pavy in this regard, and have always obtained the best results when a rigid system of urinary analysis has been instituted as a guide for the amount of carbohydrates our patients could be allowed. The urine is sent to us at regular times, and not when it suits the convenience of the patient. Is it too much to hope for that the hypodermic syringe shall be called upon to aid us, and absorption by the skin enable us to effect a cure? Shall this disease fall into the rapidly growing ranks of those that shall be influenced favorably by the hypodermic needle? Properly prepared fluid injected beneath the skin cures, or is said to cure, hydrophobia; the whole world to-day, lay and medical, is again roused from its apathy in regard to the cure of tuberculosis by the announcement from one whose utterances command the greatest respect and attention, that the subcutaneous injection of a newly found fluid will favorably influence, and cure, under certain limitations, all consumptives; and lastly, Professor Lépine has announced during the year that he is able to control the amount of sugar in the urine by the subcutaneous injection of a ferment. Hydrophobia, tuberculosis, and diabetes—hitherto regarded as incurable—are pushing themselves to the front, and the outlook is far from gloomy that they will succeed in ranking themselves with the curable maladies.

Concerning diabetes Dr. Lépine's views are of interest. Believing that the sugar is due to a deficiency in the blood-ferment, he injected a ferment beneath the skin in a man and a dog, and found in both that he could control to a great extent the quantity of sugar in the urine. Whether or not it could be thus made a curative agent is not shown, but it at least opens up a new field for thought and experiment. We have thus endeavored to point out the advances which have been made in our knowledge of, and power over, this disease, and to pass in review a few salient points which, yet remaining unsettled, are good material from which to unfold a discussion.

1010 Madison Avenue.

The Town well Named.—The story comes from Freedom, Ill., that the "ladies" of this town discovered an impostor in the person of "Dr." Moleskley, and on Easter day induced him to leave the place, after some forty of them had bombarded his office and treated him to a shower of back-number eggs.

Clinical Department.

SEVERE CATARRHAL LARYNIGITIS, ASPHYXIA, INTUBATION.

Recovery in an Infant Aged Ten Weeks.[1]

By CHARLES G. KERLEY, M.D.,
RESIDENT PHYSICIAN NEW YORK INFANT ASYLUM, MOUNT VERNON, N. Y.

The following case occurred in the New York Infant Asylum, and is, so far as I am able to learn, the youngest child intubated, either with fatal or successful result.

A delicate, poorly nourished male infant was taken sick during the afternoon of December 20th. My attention was called to the case at 7 P.M. The mother stated that the baby had been very restless during the afternoon, coughed quite hard, and nursed poorly. At this time the temperature was 100° F. One grain of calomel was given at once, and an expectorant mixture, containing four minims of syrup of ipecac to the drachm, was ordered to be given in teaspoonful doses every two hours. Counter-irritants were also applied to the throat and chest. No change of note occurred in the symptoms during the night. The temperature did not reach 100° F. No stridor or dyspnœa.

December 21st.—Examination of throat at 9 A.M. showed moderate pharyngeal congestion and slight swelling of the tonsils. Examination of chest showed rude breathing. Cough severe but not croupy; temperature ranging between 99° F. and 100° F. Slept well during night except when disturbed by coughing; temperature same as during day; nursed well; breathed easy.

December 22d.—Examination of the chest showed moist râles throughout; and of the throat intense pharyngeal congestion with considerable swelling of the tonsils. No croup or dyspnœa. Same treatment continued, with addition of spongio piline to throat; temperature 100.2° F. at 8 A.M. At 1 P.M. I was hastily summoned to see the patient, who was said to be choking, having been suddenly taken (no premonitory signs) with urgent dyspnœa and extreme cyanosis. There was marked sternal supra and infra clavicular recession, and when intubated ten minutes after the onset of the attack, was nearly moribund.

The smallest tube of the O'Dwyer set was easily introduced, with immediate relief of the respiratory symptoms, and for the extreme prostration, whiskey and oxygen were freely given. A steam spray of lime-water was immediately brought into use, and a tablet of antimony and ipecac, 1-100 grain, given hourly. At 3 P.M. a quantity of mucus was expelled during an attack of vomiting. The coughing paroxysms during the afternoon were frequent, and with each considerable mucus was raised.

The symptoms gradually improved under the foregoing treatment, the pulse becoming stronger, cough easier, and the child brighter. When intubated the temperature was 100.2° F., it was taken every two hours, and fell 0.6° during the afternoon. At six o'clock it was 99.6° F. At this time the baby nursed well with the tube in position, the body being held horizontally. At 7.30 P.M., during a paroxysm of coughing, the tube was expelled. As the breathing was fairly easy it was not replaced. The spray was kept up constantly during the night, and the tablets were given every two hours; the patient rested fair, nursed well, and vomited three times, the ejected material consisting largely of mucus; temperature remaining between 99° F. and 100° F.

December 23d.—Temperature at 9 A.M., 100° F. Patient breathing fairly easy; slight dyspnœa. At times relieved by vomiting. The tablets were stopped on account of too frequent vomiting; the spray, however, was continued constantly for next forty-eight hours. A mild bronchitis followed, which was easily controlled, and the patient was as well as usual in five days. The voice clear and normal in ten days.

OIL OF PEPPERMINT IN THE TREATMENT OF "GRIP."

By CHARLES L. HOGEBOOM, M.D.,
CEDARHURST, L. I., N. Y.

I have had much greater success in treating grip when using full doses of oil of peppermint in addition to quinine, and full doses of bicarbonate of soda, than without it. I give from five to ten drops three times a day, and sometimes more, till the worst symptoms subside. The disease may be assumed as microbic, although the germ has not been discovered. It is probably many times smaller than the typhoid bacillus, and, in consequence, may never be found.

The history of grip indicates a germ origin. It resembles, in many characteristics, other well-known germ diseases. I believe oil of peppermint to be a grip germicide. It acts with the greatest promptness and speedily dispels the most alarming symptoms, at least as far as my experience goes. The oil of peppermint is a powerful stimulant to the nervous system, particularly the vaso-motor, promoting regularity and decreased rapidity of the pulse, and relieving local congestion. It is the most diffusive of all the essential oils. These remarks are sufficient as hints to all practitioners who may care to make a trial of the remedy.

NITRITE OF AMYL IN CHLOROFORM POISONING.

By E. MAMMEN, M.D.,
BLOOMINGTON, ILL.

I desire to add another case of chloroform poisoning treated successfully by the inhalation of nitrite of amyl. The facts are as follows: At about 7 P.M. of March 13, 1890, I received a telephone message to come hastily to M. P——, who had taken chloroform and could not be awakened. The distance was about one and a half mile, and I stopped at a drug store to procure five-drop pearls of nitrite of amyl. Time of arrival was about half an hour after being called. I found the patient in a profound stupor, respirations shallow, pulse rapid and feeble. A three ounce bottle was found in his coat pocket, half full of Squibb's chloroform. A telephone message to the druggist revealed the fact that he had purchased three ounces of the drug some two hours before. He had swallowed apparently about one and a half ounce. Air was at once freely admitted to the room and to the patient, and a pearl of the nitrite given by inhalation. The effect was immediate and apparent. After the lapse of fifteen minutes, pulse again became rapid and feeble, and another pearl was used, with the result of deepening the respirations and increasing the vigor of the pulse. The same thing was repeated at lengthening intervals eight or nine times. Meanwhile hypodermic injections of atropia were twice given, and towels wrung out of cold water dashed upon the chest. After four hours the patient awoke from his stupor, and in another hour was out of danger. Recovery was somewhat slow, owing no doubt partly to the great destruction of red blood-corpuscles, as evidenced by the extreme icteric hue of the skin, which persisted for two weeks. In my judgment this patient could not possibly have survived without the use of nitrite of amyl.

A CASE OF HEART DISEASE WITH PULMONARY ŒDEMA, RELIEVED BY OXYGEN INHALATION.

By WILLIAM T. S. WARDWELL, M.D.,
ROSLINDALE, MASS.

Dr. F. M. Johnson's article in the Medical Record of January 17th, recalls a similar case which occurred recently in my own practice. On Friday, December 26th,

I was called to see Mrs. C——, twenty-nine years of age, and weighing about one hundred and ninety pounds. She had a history of acute rheumatism at the age of ten years. I found her sitting up, with breath quite short, about 35; pulse, 110. No fever. She complained of discomfort in the cardiac region and palpitation on moving. She also had considerable lameness in her wrist joints, which were not swollen. She stated that she had had a number of previous attacks which had not necessitated the calling in of a physician. Upon auscultation I found the second aortic sound replaced by a murmur, which was transmitted a short distance toward the apex. The usual cardiac stimulants were prescribed, and I did not see her again until the 28th, when I found her bolstered up in bed, respiration, 50; pulse, 120; temperature, 100° F. The diagnosis of aortic insufficiency, with possible myocarditis, had been made, but on re-examining the patient I found the murmur had disappeared, possibly being masked by the mucous râles which were now present over both lungs.

Her condition continued about the same until December 31st, when the temperature in the morning rose to 103° F.; pulse, 130; respiration, 60. On the following day, January 1st, I called Dr. Henry J. Broughton, of Jamaica Plains, in consultation, who confirmed my diagnosis, and at his suggestion a cylinder of oxygen was procured and used intermittently, with excellent results as far as rendering the patient more comfortable. Death ensued quietly on January 8th, thirteen days after my first visit.

From my experience in the above case, I can heartily testify to the palliative effect of oxygen in cases of pulmonary œdema, and shall consider it my duty to use it when other remedies fail to relieve, even should I know that the condition of the patient is hopeless.

Progress of Medical Science.

The Characteristic Organism of Diphtheria.—An inquiry into this subject has been made by Dr. Jabez Hogg, and printed in the *Medical Press and Circular*, January 28, 1891. From French and German sources comes the news that the specialized bacillus of diphtheria has at length been grasped, and is about to take its proper place in pathology. Earlier, the medical profession have shown much unwillingness to admit a pathological difference between diphtheria and croup, diseases in reality separated by wide and distinctive differences. Diphtheria is epidemic and endemic, attacking persons of all ages, while croup proper is essentially sporadic and non-contagious, and usually met with during childhood. The nomenclature should be as different as the symptoms and pathological changes. To designate one diphtheritic membranous laryngitis, and the other simply croupous laryngitis, would be a convenience. Diphtheritic membranous laryngitis undoubtedly partakes of the fibrinous form of exudation, while the croupous membrane is for the most part corpuscular. The felt-like false membrane of diphtheria is made up of a net work of connective tissue, elastic and non-elastic fibres, in the meshes of which are entangled layers of altered epithelium cells, blood-corpuscles, fat cells, and numerous foreign bodies, conspicuous among which are starch granules or other particles of food and fungi. This membrane is undoubtedly a laminated fibroid tissue embracing superficial and deep seated structures. The opinion generally held is that micro-organisms found in connection with the diphtheritic membrane are common to, and not to be distinguished from, those found in other forms of disease, as erysipelas, pyæmia, variola, and tuberculosis.

The Dressings used at Billroth's Clinic.—1. Iodoform gauze: this is first sterilized and then soaked in the following mixture: Iodoform, 50 grains; glycerine, 100; alcohol, 400; then squeezed and dried with sterilized cloth. 2. Adhesive iodoform gauze (colophonium used in its preparation). 3. Tannin iodoform gauze. Silk: This is almost the only thing used for sutures, etc. It is disinfected as follows: Boiled in five per cent. carbolic lotion for an hour, then wrung out with disinfected hands, and boiled for another hour in five per cent. carbolic, then left for fourteen days in carbolic lotion, when it is ready to be used. Catgut: First washed with potash soap, then laid twice for twelve hours in ethylic ether, then dried and sterilized in a dry chamber by raising the temperature to 250° F., then laid in 1 to 1,000 sublimate for twenty-four hours, and finally kept for use in absolute alcohol. Instruments before laparotomy to be boiled for one hour in five per cent. carbolic lotion. Silk, catgut, and instruments during the operation placed in two and half per cent. carbolic lotion, not in five per cent. as was previously done. Needles, clamps, saws, lie always in fifteen per cent. carbolic glycerine. Hypodermic needles, and syringes kept in fifteen per cent. carbolic oil. Drains kept at least fourteen days in carbolic lotion before use and always remain therein. Sponges not used, hydrophile gauze being employed instead. Pieces are folded (10 fold), sterilized in the hot oven, and then boiled for one hour in carbolic lotion, five per cent.; then kept in carbolic or in sublimate, ten per cent., and just before the operation placed in a 1 to 3,000 sublimate solution. During the operation the wound is washed in a 1 to 3,000 —5,000 sublimate solution, which is also used for the hands, tartaric acid being added to the lotion as well as fuchsin to color it.

Relation of Stomach Disorders to Affections of the Male Genital Organs.—Professor Peyer claims to have demonstrated reflex neuroses of this kind in over three hundred cases. He points out the close, and frequently observed, connection between disease of the female generative organs and the stomach, and claims that a similar relation is to be observed in the male. The principal cause of these neuroses he finds in onanism, abusus sexualis, and coitus reservatus. The symptoms relating to the stomach are atony, gastroplegia, nervous vomiting, eructations, cramps, and the secondary disturbances of these conditions. The diagnosis is oftentimes difficult, but may be made by the presence of the products of chronic urethritis in the spermatic urine. Therapy is to be especially directed to relieving the local sexual disorders, and the condition of the nervous system.—*Volkmann's Sammlung Klinischer Vorträge.*

Typhoid and Pseudo-Typhoid Bacilli in River Water.—Dr. Cassedebat, following up Rietsch's work on the river waters of Marseilles, gives the result of an examination of seventy specimens of water, from which 250 cultivations were made, with a view of determining whether the Eberth bacillus is to be found in the waters of the Durance, which supply a part of the city where typhoid fever is endemic and often epidemic (*British Medical Journal*). In no case was he successful in finding the Eberth bacillus, but he was able to separate three bacilli —"pseudo typhoid bacilli"—which resemble the typhoid bacillus in many respects; like it, they can all withstand the action of pretty strong carbolic acid. They all present clear spaces or deeply stained masses, which might readily be taken for spores; but they and the true typhoid bacillus containing these bodies are all killed at a temperature of a little over 113° F. They stain equally badly by Gram's method. They have a lateral and oscillatory motion as well as the forward motion. The plate cultivations are so much alike that unless all four can be seen together it is difficult to distinguish one from the other. On potatoes, in broth, and in milk, they are alike, except that they develop with different degrees of rapidity and vary somewhat as regards the alkalinity and acidity of their products at the end of about thirty days, and also as to the degree and time of appearance of the turbidity produced in broth. There are differences, how-

ever, to be observed in these organisms grown in broth or milk to which small quantities of the various aniline staining reagents have been added. The ordinary cultivation methods are sufficient to distinguish these four forms from others for which the typhoid bacillus has at times been mistaken. None of the pseudo forms are quite so toxic to white mice as the true form, and one of them is quite innocuous. Although Cassedebat was not able to find the true form in water taken from the water supply which was most open to contamination, he found that this was not because bacilli could not live in water, as in distilled water, to which a cultivation had been purposely added, he could easily distinguish its presence at the end of forty four days, and when added along with half a dozen other forms he could find them at the end of seventeen days. He comes to the conclusion, therefore, that the true typhoid bacillus does not occur in water so frequently as is sometimes represented, and that one or other of the forms of pseudo-typhoid bacilli has in certain cases been mistaken for it.

The Vaso-Dilator Action of Urea.—The researches of Abeles and Munk on the effect of urea in the blood upon the renal vessels, causing them to dilate, have recently been supplemented by Drs. Cavazzani and Rebustello, who have made a series of observations in the physiological laboratory of the University of Pavia, upon the effect of urea, when circulating in the blood, on other vessels in different parts of the body (*The Lancet*). They find that a vaso-dilator action is produced similar to that observed in the renal vessels, but less marked in extent. The greatest effect is observed in the cerebral vessels, and the least in the vessels supplying the limbs, the hepatic vessels being affected to an extent intermediate between the two. Generally speaking, the effect is directly proportionate to the amount of urea in the blood; but the hepatic vessels seem to present an exception to this rule, for the dilatation in them appears to be about the same whether the percentage of urea in the blood is high or low. The greater the quantity of urea, and the more marked the action, the sooner the effects pass off. With reference to the various organs, the effects pass off first in the cerebral vessels and in the vessels supplying the limbs, next in the renal vessels, and last in the hepatic vessels. In the renal vessels the acceleration of the circulation produced by the urea is most marked when the blood pressure is low. The smallest dose of urea which will produce vaso dilator effects is not the same in different parts of the body; thus, one part per thousand of blood is necessary in most of the viscera, but in the kidneys half that amount is sufficient.

Phagocytosis and Immunity.—The fact that one attack of a contagious malady, such as small pox or scarlet fever, renders an individual immune against a second attack has never received adequate explanation. It is even more difficult to explain satisfactorily the immunity conferred on an animal by inoculating it with the attenuated virus of a disease which in its ordinary form is often, and in a few cases invariably, fatal, such, for instance, as protective inoculation for anthrax, chicken cholera, and the older method of vaccination to protect from or modify an attack of small-pox (*The British Medical Journal*). In a lecture recently delivered by Dr. Metschnikoff at the Pasteur Institute, an attempt is made to prove that the defending powers exercised by the amœboid cells of the organism are in a large measure concerned in conferring this immunity. The aggressive characters of these amœboid cells has earned for them the name of "phagocytes," and Metschnikoff points out that they are of different kinds, and originate in various ways. In connection with the subject of immunity, it is important to remember that these phagocytes can include and destroy micro-organisms; but the more malignant the micro-organism the more rarely is it found within the phagocyte, and this is especially true of such diseases as chicken cholera, hog cholera given to pigeons and rabbits, and anthrax of mice. All these diseases have the character of general acute septicæmia and cause death within twenty or thirty-six hours. According to the views expressed in this lecture, we are to believe that when the micro-organisms are attacked by the phagocytes, an animal may recover from the disease. In the maligrant forms, where the phagocytes do not intervene—that is, phagocytosis or amœbic warfare is not established—then the bacteria overrun the organism, and induce death. This partiality of the phagocytes is attributed to their sensitiveness to external influences, and especially to the chemical composition of their environment. These cells are powerfully attracted by many micro organisms, and repelled by others. This attraction and repulsion are expressed by the terms "positive chemiotaxis" and "negative chemiotaxis." Now the basis of the theory appears to be that the chemiotaxis of the phagocytes of a given animal is mutable, and that cells may be gradually attracted to substances in a mild form from which they shrink when presented to them in a concentrated form. Hence by inoculating an animal with an attenuated virus the chemiotaxis, previously negative, will acquire positive characters, and at last be induced to attack the micro-organism of a malignant disease should occasion arise. Any attempt to explain immunity from infectious diseases on a rational basis will be very welcome. The theory propounded by Metschnikoff is, like all the previous communications made by him on the subject of intracellular digestion, the outcome of patient and industrious observation, and must command our attention. His views, formulated for the first time in a consecutive manner in this lecture, promise to revolutionize opinions as to inflammation and fever, and this attempt to explain the power of the cells to confer immunity from infectious diseases is sure to be hotly contested, for every important contribution to this confessedly obscure subject must necessarily be in a large measure hypothetical.

Ferric Bromide.—Dr. Hecquet strongly recommends the perbromide of iron, or ferric bromide, in many affections in which it is desirable to soothe without depressing, and to strengthen without exciting. Out of 25 cases of spermatorrhœa treated by this drug, 19 were completely cured, 2 only being unrelieved, and in these cases complications were present in the form of prostatic enlargement and stricture of long standing. The perbromide was frequently found useful in cases of chloro-anæmia, leucorrhœa, hysteria, amenorrhœa, hydræmia of pregnancy, chorea, epilepsy, diabetes, and tuberculosis. In conjunction with Dr. Vacossin, a series of trials were made in the Abbeville Hospital on its action in cases of cardiac hypertrophy, with the result that Magendie's observations, made more than fifty years ago, were confirmed, the patients being strengthened and relieved by the calming of the palpitation and of the dyspnœa. This combination is well borne, even by irritable stomachs. It may be taken in solution, or in lozenges, the dose being from three to five grains. The action is more rapid than that of most iron compounds, as its good effects begin to manifest themselves in cases of chlorosis during the first week of administration, a complete cure being generally obtained in a month. Dr. Hecquet has found by experience that the ferric salt, Fe_2Br_6, acts both more rapidly and gives more permanent results than the ferrous salt, $FeBr_2$, and hence he has latterly confined himself to prescribing the former, which he does not hesitate to say is endowed with exceptionally valuable properties, and deserves to be far better known and more employed than it has hitherto been. There is a preparation of the ferrous salt in the Pharmacopœia of the Pharmaceutical Conference, which, however, is not very largely prescribed.—*The Lancet.*

Revue Internationale d'Electrotherapie is the name of a monthly journal edited by Georges Gautier, and devoted chiefly to gynecological electricity.

THE WORK OF LEUCOCYTES.

A STUDY of the relation of bacteria to disease is of great interest, and sheds abundant light, not only on the nature of specific diseases, but also on that of inflammation. In "Evolution and Disease," J. Bland Sutton reviews the leading facts connected with the evolution of the inflammatory process as manifested by a complex organism. Most complex organisms are pervaded by a corpusculated fluid, which may circulate throughout the organism by traversing lacunar spaces, or by means of narrow tubular passages possessing distinct walls. This fluid serves as a living medium to all parts of an organism. The red blood-corpuscles carry oxygen, as is well known, and the white fulfil some very extraordinary functions. Should a portion of an animal die, leucocytes attack it; and if it be small, will cluster round and, by a process of intracellular digestion, devour it. If the part to be removed is large, leucocytes effect a separation between it and the living body. Not only are dead or damaged portions of tissue thus disposed of, but useless parts—such as the tails and gills of tadpoles, remains of larval organs, and the tails of ascidians—are slowly removed by the same process. Animal tissues are incapable of resisting an attack of leucocytes. An examination of the milk-teeth of children or puppies at the time they are shed, will attest the digestive powers of these cells. An ordinary magnifying-glass shows the irregular edge of the crown to be full of bays and recesses; and the microscope reveals the presence in these spaces of leucocytes, which during life were busily engaged in destroying the fang of the tooth and thus causing it to fall out. Small pieces of clean sponge introduced into animal tissues disappear in a few days; while indigestible objects—glass, needle, or fragment of metal—are surrounded by large numbers of leucocytes that are soon transformed into neutral tissue which isolates the intruders from neighboring parts. Should the intruded body contain particles of dirt offensive to these cells, their action is intensified to a degree highly disastrous, for they die in the conflict, and in a few hours the foreign substance is surrounded by a fluid—pus—containing the dead cells. When this fluid is evacuated, the cause of all the disturbance often escapes.

Leucocytes, in their behavior to foreign bodies, may be compared to bees. When the offender is small, it is quickly stung to death and cast out. When large, it is deprived of life and rendered innocuous by a covering of wax. Leucocytes also attack pathogenetic bacteria, and attempt to destroy them. This amœbic warfare may be described from attacks actually witnessed by Metschnikoff in the water-flea *Daphnia*. Spores gained an entrance into the body of the crustacean, germinated, and were dispersed by the blood over the body (in daphnia the blood circulates in lacunar spaces), and deposited where the blood moves slowest, viz., in the cephalic and hinder portions of the mantle cavity. In these places heaps of conidia collect. The leucocytes are not idle. They attack and devour the conidia, take them into their interior, and digest them. If a conidium is too much for one cell, others join it, form a giant cell, and thus struggle with the invader. Should the leucocytes overcome the spores, the daphnia lives. If not, the conidia overrun the crustacean and death is the result.

Similar processes in animals more highly organized take place, the defending power of leucocytes being well illustrated in avian tuberculosis. Tuberculosis is unfortunately widespread in man; but in birds, especially those that live on grain, it is more common than in human beings The liver and intestines of birds that have met their death from this cause, present numerous pale-yellow, rounded nodules, the centres of the larger ones containing pus. The smaller ones are homogeneous, containing in the centre small circular cells with larger ones—giant-cells—lodged among them; outside these a layer of smaller cells; and, lastly, a layer of fibrous tissue. The microscope reveals minute bacilli clustered in the centre of the mass and occupying the interior of the cells, especially the giant-cells. In nodules of moderate size, caseous material surrounded by a zone of cells containing bacilli, occupies the centre. Adjacent nodules may coalesce and thus produce large masses. Blood-vessels connected with the nodules frequently present clusters of bacilli in their interior. The author (Sutton) is convinced that these bacilli, from whatever source arising, are introduced into the alimentary canal and find their way into the walls of the intestine. Here they are attacked by the leucocytes, which surround, ingest, and destroy them. The bacilli may be too numerous for the leucocytes, and the point where they gain entrance into the tissues be transformed into a battle-field. Large numbers of other leucocytes quickly reinforce their comrades. Many of these die, others fuse and form giant-cells. The dead leucocytes form pus cells and give rise to the caseous centre in the nodules. From these nodules the bacilli are conveyed by blood-vessels, or are even carried away by the leucocytes—a giant-cell sometimes containing fifty bacilli—and initiate new struggles in distant parts. When bodily conditions are favorable, bacilli multiply very rapidly and overrun the whole system, nodules arising in the liver, lungs, brain, and skin. Function is interfered with and death results. In addition to local troubles, bacteria produce general disturbances, one of the most important being fever.

The behavior of leucocytes to pathogenic bacteria constitutes the essence of the inflammatory process. This is essentially a local struggle between irritants and the white cells of the blood. When the whole of the blood is engaged in the struggle—as in ague, pyæmia, anthrax—we have general inflammation or fever. The different varieties of fever depend on the habits of the bacteria, some

being virulent or irritating to the tissues, and others slow in attaining maturity. Inflammation takes place in plants; for example, the galls on leaves due to the deposition of eggs in their interstices by insects. Each insect produces in this way a different kind of gall. One leaf may thus present at the same time several varieties of inflammation. It simplifies our notions of morbid processes to find that the phenomena known as the repair of wounds, inflammation, and fever, are manifestations of the same process by which a child loses its milk-teeth, the tadpole its tail, or the stag its antlers, rather than to look upon such conditions as the result of some special law.

NEURASTHENIC STIGMATA.

Recent issues of the *Union Médicale* contain a *résumé* of Dr. Bouveret's lectures on neurasthenia. While the symptoms of this interesting disease are extremely varied and numerous, according to Dr. Bouveret's view there are certain distinct manifestations which are sufficiently constant to be called the stigmata of neurasthenia. These are headache, insomnia, muscular weakness, vertebral pain, atonic gastro intestinal dyspepsia, to which are frequently added habitual dilatation of the pupil owing to feeble reaction to light, together with discoloration and objective and subjective coldness of the hands and feet.

While the headache is more or less persistent, the pain is not particularly severe, the sensation being more that of heaviness, fulness, and constriction, as of a hand or cap pressing upon the scalp, giving rise to what Charcot calls the helmet symptom. In event of intense headache, which sometimes exists, it is circumscribed, may be limited to the forehead, one temple or both, to the occiput, or the back of the neck. Aching and weariness in the neck are common, and in themselves are rather good signs of neurasthenia. The neurasthenic headache is increased by work, intellectual effort, noise, and sudden emotion. During these exacerbations vertigo is not infrequent. True migraine may complicate this cephalal gia and render the condition doubly trying. Insomnia is of the persistent order, and is rebellious to treatment. It may be absent in women. In certain rare cases, irrespective of sex, the fatigue of work is followed by attacks of irresistible somnolence. Dreams are common, and more or less distressing. Sleep may come only toward morning, or it may visit the patient early in the night, leaving him to the horrors of wakeful visions after an hour or two. In either case the sufferer rises unrefreshed, in a condition of extreme weariness, without energy and without hope, and as thoroughly sapped as if he had been up all night.

Mental depression in neurasthenia expresses itself as exhaustion of all the mental faculties. There is loss of memory, of judgment, of will, inability to fix the attention for any length of time, and to resist sufficiently the influence of psychic impressions. Impairment of will is the keynote to the psychic state in neurasthenia. It is impossible for the patient to pursue the even tenor of his way. The character changes. The thousand and one petty annoyances of daily life are converted into so many excuses for irritability, anger, and exhibitions of bad temper. General weakness exists, and a notable diminution in muscular force is usually present. After slight emotion, moderate physical fatigue, sometimes without assignable cause, there will come a sudden feeling of profound prostration and complete loss of strength, together with painful fatigue in the calves, knees, and thighs. Vertebral pain is almost as common as headache. It is a sensation of heat, burning, lassitude, and strain along the spine. This has favorite points of location: the seventh cervical vertebra, the lumbar vertebræ, and the sacral region. It may exist in the coccyx alone.

There are two forms of neurasthenic gastro-intestinal atony. In the first, only functional disturbances appear. In the second, the patient emaciates, loses strength, and objective symptoms are present. Abdominal examination reveals prolapse and dilatation of the stomach, flabbiness of the anterior abdominal parietes, together with descent of the kidneys and liver in certain instances, completing the anatomical complexus that Glenard has described under the title of enteroptosis. There are cases, not so rare either, where after the earliest developments of neurasthenia, the patient passes progressively and rapidly from functional gastro-intestinal atony to enteroptosis of serious moment.

A chemical hypothesis to account for neurasthenic phenomena has recently been proposed by Professor Kowaleski, of Charkow, of which mention appears in the *American Journal of Insanity*, January, 1891. Acquired neurasthenia may be divided into two principal varieties: one where there is excessive mental strain or exertion without sufficient nourishment. The brain is starved with the rest of the body, and naturally fails to perform its functions. The other form of the disease is found in those who lead lives of intense mental activity within a narrow field, and who have but little physical exercise. The tendency of modern civilization to specialism leads to the restricting of mental activity to a limited range of topics, tending to local exhaustion of the brain. This exhaustion may come about in spite of an abundant supply of food. In consequence of the sedentary lives led by persons engaged in intellectual pursuits, food may aggravate the evil, poisoning the brain by imperfectly assimilated material. Alcohol, tobacco, tea, and coffee taken to stimulate flagging energies, together with late hours to make good the losses of the day, serve to render bad matters worse. The congenital form of neurasthenia, when not connected with anatomical anomalies of the nervous system that can be demonstrated, must be considered due to defect of organization that conjecture may reasonably ascribe to its abnormal chemical constitution. In view of the frequent appearance of neurasthenia and allied disorders among children of drunkards, it seems probable that poisoning of the nervous system of the parent may result in defective chemical composition of the nerve-elements in the offspring, this being latter-day retribution following the eating of sour grapes by modern fathers.

ARSENIC IN WALL PAPERS AND CLOTHING.

Arsenic seems to be the bugaboo of the Massachusetts physician. Not long ago the Board of Health of that State made an elaborate report upon the subject of arsenical wall-papers and showed how fatal they were to hu-

man health and happiness. More recently a Dr. Talbot has been making some portentous statements regarding the same poison. This is the gloomy and green-eyed way in which the gentleman looks at the subject :

"We sleep in bedrooms the walls of which are hung with paper filled with arsenic. Our most beautiful draperies are equally loaded with this poison. We sit upon sofas that every time they are compressed throw into the atmosphere this same poison. We wear clothing containing enough arsenic, if taken into the stomach, to produce a speedy death. Our little children are wrapped in beautiful shawls containing this same death-dealing drug. Their playthings are rendered more beautiful and attractive by this very poison. The papers in which their bon bons and candies are enveloped are colored with arsenical preparations. I saw to-day at the Board of Health a wrapper of checkerberry lozenges containing two grains of arsenic. Even the utensils in which our food is cooked are sometimes lined with this poison."

Now all this sounds very alarming, but is there not in it a good deal of what may be called sensational sanitation ?

Arsenic is prescribed a great deal to children and adults. It can be given in small doses for a long time with only beneficial effect. It is said to increase the appetite, promote nutrition, clear the skin, and cure chlorosis. It is given systematically as a prophylactic in malarious countries.

If there is arsenic in wall-paper most of it stays there. It does not volatilize and can only reach the air in the form of a dust.

It is a curious fact that workers in arsenical colors, according to Dr. Tracy, rarely suffer from general symptoms of arsenical poisoning, the troubles in this class being mostly those of ulcerations and cutaneous eruptions. When general symptoms do appear they differ in a good many ways from those of so-called chronic arsenical poisoning.

Arsenic is poisonous and dangerous when employed in coloring clothing, artificial flowers, or toys; but the periodical alarms over arsenical wall-papers are usually based on the fear-stricken imagination of some ecstatic sanitarian who has found arsenic in a piece of paper which lay in the house of a person who was ill.

We may add that the following simple test for the presence of arsenic is given by Professor Calder, of Brown College, and may prove of practical service to our readers.

If hydrochloric acid, a piece of copper wire, and a bit of wall paper containing arsenic be placed in a glass tube, and the glass be gently heated, the wire will be blackened.

A FLOW OF CHYLE FROM SKIN AND KIDNEYS.

From time to time cases are reported in the medical journals in which a milky fluid has flowed from incisions into the living body, or has escaped from various portions of the surface through natural or newly formed passages, or has been found post mortem in the cavities of the cadaver. The only natural fluid of the body (with the exception of the mammary secretion, which is not under discussion) to which this milky fluid can correspond is the chyle ; and, indeed, repeated examinations have proven that the fluid in question is in every respect identical with the chyle. The determination of the manner in which the chyle escapes from its natural channels, and of the causes which lead to its escape, has brought to light some very interesting facts, although at certain points and in particular cases the process is still shrouded in obscurity.

Normally, the chyle is confined in the lacteals, which absorb it from the intestinal walls and pour it into the receptaculum chyli, and to the thoracic duct, which conveys it from the receptaculum chyli upward to the junction of the left internal jugular and left subclavian veins, where it is mingled with the blood-stream. It is easy, therefore, to understand how, in consequence of rupture of the thoracic duct or lacteals from any cause, as direct injury, disease of the vessel-walls, or even obstruction which caused undue fulness of the vessels, the chyme might escape into the tissues or cavities of the thorax and abdomen.

The puzzle is to show how it can make its way into the tissues of the lower limbs and into the excretory ducts of the kidneys. The escape of chyle from the surface of the lower limbs has been observed in only a few cases. In Da Costa's "Medical Diagnosis" reference is made to a case, reported by Dr. Day in the *Transactions of the London Clinical Society*, vol. 2, 1869, in which there was enlargement of the leg, distention of the subcutaneous lymphatics near the groin, and a formation of vesicles which were connected together by ridge-like elevations and from time to time discharged a chylous fluid. Chyluria is a frequent complaint in certain tropical countries, and numerous cases have recently been observed in South Carolina.

A case related by Dr. Myers, of Indiana (*British Medical Journal*, September 13, 1890), is especially remarkable, since it presented, first, a discharge of chyle from the leg, and afterward, when this ceased, chyluria.

The patient, a woman of Scotch descent, was healthy until her eleventh year, when she suffered from a pain on the outer side of the left thigh, for which, under the title of sciatica, she was treated off and on for five years. She then came under care of another doctor, who put a seton into the upper portion of the left thigh. During this operation a quantity of milky fluid escaped from the wound. The left lower limb was at this time larger than the right, especially after exercise. Twenty or more small prominences of a vesicular character appeared upon the inner and outer aspects of the upper portion of the left thigh and from them a daily discharge of milky fluid occurred. The fluid, which ran more freely after dancing or long walks and amounted sometimes to ten or twelve ounces a day, was upon chemical analysis shown to be chyle. After the more profuse discharges, the patient suffered from languor and anorexia and would be confined to bed for several days.

Recently, after an illness lasting several months, a sudden and permanent cessation of the flow from the thigh had been observed, and in its place chyluria appeared. The chylous urine had been passed daily ever since in large quantities, the urethra being often blocked by coagula formed in the bladder. The urine would, on standing in a vessel, become semi-solid from coagulation. On examination, it was slightly pinkish from the presence of

blood, and cloudy from the presence of large quantities of chyle. Its transparency returned when it was shaken with ether. It contained no casts. Repeated examination failed to show the presence of Filaria Sanguinis Hominis. The periods when the flow was greatest were marked by chill, low temperature, pain in the back, mental depression and extreme restlessness, followed by quickened pulse and increased temperature. Dr. Myers doubts the renal origin of the discharge, but thinks it due to a fistulous opening of the delicate lymphatics and lacteals in the lumbar region, high up, near or at the thoracic duct.

In the opinion of the present writer his theory is obscure and unlikely. The true explanation seems to be somewhat as follows:

The receptaculum chyli receives not only the chyle-bearing lacteals from the intestines but also the lymphatic vessels from the lower limbs and likewise from the kidneys. It is comparatively easy to see how, in case the thoracic duct were obstructed in any part, the mixture of lymph and chyle in the receptaculum chyli might be dammed back into the lacteals of the lower limbs or kidneys, overcoming the resistance of their delicate valves and escaping either by fistulous channels through the skin or by the excretory ducts of the kidneys. It may be that there is some inherited or acquired weakness of the walls of the lymphatic vessels or insufficiency of their valves in the affected parts of the body, which permits a reflux of the contents of the receptaculum chyli whenever the blood-pressure is increased in the venous trunks into which the thoracic duct empties. Chylous congestion of the lymphatics of the muscles and of the kidneys has followed ligature of the thoracic duct in aged dogs, and dilatation of certain of the vessels which empty into the receptaculum chyli has been known to result from venous congestion in certain cases of heart disease.

In any case of flow of chyle from the lymphatics (not lacteals) of the lower part of the trunk or of the abdominal organs the following points are to be considered in seeking a diagnosis:

1st. Are the lymph channels blocked or their walls enfeebled by Filaria Sanguinis Hominis?

2d. Is any tumor pressing upon the thoracic duct?

3d. Is there any disease of the walls of the thoracic duct?

4th. Is there any increase of venous blood-pressure which hinders the outflow of chyle from the mouth of the thoracic duct?

5th. In the absence of the preceding causes, is there an inherited or acquired weakness of the walls or valves of the lymph-vessels which drain the part from which the chyle escapes?

The treatment varies with the diagnosis and cannot be considered in this article.

VENESECTION AGAIN.

Venesection tries very hard to get upon its feet again. Every now and then we come across an article or a discussion in which this ancient therapeutical stand-by is petted and praised and coddled; but after this comes silence again. The pride and staff of our forefathers seems to remain in hopeless senility. Phlebotomy does not get popular. Medical fashions, we are told, run their course, and after a time reappear. Calomel has been taken up again, and perhaps as many people take mercury now as ever, though in more modest doses. But the modern doctor still will not bleed.

At a recent meeting of the Royal Medical and Chirurgical Society, Dr. Pye-Smith told us again how useful venesection is. He reports fifty cases! Half a century ago every country doctor could report as many in a year. Dr. Smith thought venesection indicated in cyanosis with distention of the right side of the heart, whether from pulmonary or from some other obstruction to the circulation; in the intense pain of thoracic aneurism; and in uræmic and prolonged epileptic convulsions.

Dr. Stephen Mackenzie and Dr. Broadbent confirmed the views of Dr. Smith. With such authorities, perhaps, there will be a little more phlebotomy, at least in our hospitals. But its use in private practice will be limited for a long time to come.

THE LAW AND THE INSANE.

The so-called Stephani case has very naturally excited a good deal of interest and discussion in this city of late. Last July a young man named Stephani shot and killed a prominent lawyer in his office. Stephani was arrested, his counsel put in a plea of insanity, and he was examined as to his mental condition by a commission appointed by the district attorney. This commission called a number of experts, who all testified to Stephani's insanity, and a report to this effect was made; the findings were set aside, however, and a new commission appointed, which also called experts, and these again testified to the insanity of the accused. Nevertheless the commission reported him as sane, and Stephani was tried recently before a jury, which pronounced him guilty of murder. The extraordinary and interesting feature of the case is the rare and delightful unanimity of the medical experts as to the man's insanity. Eight or nine of the leading alienists and medical experts of this city examined him, and all pronounced him insane. It was shown to the jury that he had had an insane brother, that he had had epileptic fits, had had delusions of persecution, and had been considered irrational for several years by prominent physicians attending the family. The whole burden of medical and expert evidence was overwhelmingly in favor of the insanity of the man. Yet the jury promptly decided him to be sane, and the only question raised was whether he should be hung or be declared a murderer in the second degree.

Some vigorous protests have naturally been made against a decision so grossly antagonistic to facts and evidence. But it is a decision quite in accordance with others. The average juryman thinks he knows rather more about insanity than men who spend their lives in studying it, and many judges are inclined to encourage such views. This has resulted in part from the laxity exercised in selecting experts, or in admitting as experts persons who have no claim to such title. In part it is the natural outcome of the legal view taken of insanity, according to which some insane men are responsible, and some sane men irresponsible, depending upon the eloquence of the lawyer, the bias of the judge, and the attitude of the jury.

STRONGER STIMULANTS.

Every physician is confronted frequently with cases of profound collapse, or dangerous weakness. The patient may be suffering from surgical shock, or severe hemorrhage, or a great physical injury, or may be in the critical stage of a pneumonia, or infectious fever, or there is a sudden giving out of a damaged heart. What can be done in these cases? This query is raised by Dr. W. H. Burr, of Wilmington, Del., in the *Medical and Surgical Reporter*.

A good example to work on, he says, is the case of a patient exhausted by previous disease, who is compelled to undergo a serious operative procedure as an only chance to save life. We have here three elements to combat. Exhaustion from previous disease, shock from operative procedure, and anæsthetic influence. What drugs, if any, either by stomach, rectum, or hypodermically, are most efficient to help tide the patient over the emergency? One author says alcohol finishes those who escape the anæsthetic effect; another prominent author uses alcohol very freely, and proves his theory by an experience covering thousands of cases. One author recommends hypodermic injections of ammonia, and another digitalis.

Another good example is the heart failure in pneumonia. Here a prevalent practice is to give digitalis; yet one or two high authorities strictly condemn its use.

The list of stimulants recommended in various asthenic conditions is a very long one. It includes alcohol, digitalis, ether, ammonia, camphor, nitro-glycerine, strychnia, musk, oxygen gas, bleeding, cups, electricity, hot applications, artificial respiration, etc. Yet how often it is that all those remedies not only fail, but seem to make no impression. The patient gets an ounce of whiskey every hour, ten drops of digitalis every three hours, or perhaps nitro-glycerine every fifteen minutes, oxygen gas is administered perhaps continuously, and still there is no response, but the vital forces sink steadily. When this happens, the doctor shakes his head and says it is of no use, the patient must die. And he is right, the patient does die; yet often it seems as though our art ought not to be so futile. Thus, in cases of pneumonia collapse comes on when the patient was apparently doing fairly well, and if life could be prolonged twenty-four hours the disease would perhaps take a favorable course.

Here is a problem, then, for therapeutists to work out. Can there not be devised or discovered more powerful stimulants than we now possess? Are alcohol and ammonia our last resorts? We believe not. He who discovers something twice as potent will do as great a service to mankind as Jenner, and with all due respect to "tuberculin," a much greater service than Koch.

THE GERMICIDAL POWER OF THE BLOOD.

The blood is known to have germicidal properties, and these properties have recently been studied by Von Fodor, who reaches some interesting conclusions. He finds that increased alkalescence of the blood raises its germicidal power very much. The drugs which do this most effectively are the carbonates of sodium and of potassium. By the alkalinization of the blood of rabbits he made a large per cent. of them refractory to anthrax. Hydrochloric acid had no effect on the germ-destroying power of the blood, while quinine actually lessened it.

These observations are of interest in connection with the observations of Bordas, who asserts that he has discovered the specific microbe of acute rheumatism, it being, he thinks, an organism allied to the micrococcus pyogenes.

On the other hand, the statement that quinine lessens the germicidal power of the blood is absolutely untrue, as regards the plasmodium of Laveran at least. We are accustomed to think also that hydrochloric acid is a good drug to take in order to prevent the infection of cholera and other germs which get in by way of the stomach. Von Fodor's observations, therefore, cannot have a general application.

He states that temperatures up to 39° C. or 40° C. also increase the fighting power of the blood against pathogenic organisms.

ASTHMA A NEUROSIS.

In these days, when it is the vogue to attribute to the nose all lesions of the respiratory apparatus below it, and when asthmatics in particular rarely escape without applications of saw and cautery, it is worth while to call attention to the observations collected by Professor Brissaud in the *Revue de Médicine* for December, 1890. This gentleman shows that a large portion, if not all, victims of essential asthma are neurotic, and that a nervous irritability is at the base of their trouble. The facts of heredity, the history of alternations of asthma with other neuroses, such as hysteria, neuralgia, insanity, etc., are brought in to support Brissaud's views.

There is nothing particularly novel in this, but overmuch force has often been placed upon diathetic and reflux influences, and the neurotic theory is probably nearer the true one for the majority of cases.

The rational cure of asthma must be based on attempts to relieve the neuropathic taint. For the palliation of the symptoms, however, and the lessening of attacks, we must still rely in most cases upon climate, diathetic remedies, and in some instances upon treatment of nasal or other local disorders.

News of the Week.

One of our Practical Country Practitioners from one of the upper counties in this State was recently on a visit to New York, and, among the other wonders of Gotham, took in one of the gynecological clinics. It was one of the professor's field days, and, at the conclusion of a brilliant clinic, he asked Dr. F. "what he thought of medical matters in the metropolis." Dr. F. replied: "Well, I would rather be a moonshiner down in Tennessee than a uterus up here in the hands of you New York doctors."—*Southern Practitioner*.

A City where Doctors are Appreciated.—A Philadelphia physician has just received a legacy of $10,000 from one of his patients.

"The Pink Eye" is prevailing among the horses of Philadelphia.

New Medical Law of Alabama.—The *Alabama Medical and Surgical Age*, February, 1891, says that the "Penalty Bill," which recently passed the Legislature, gives Alabama a model medical law, and places the State Medical Association on a safe and sound basis. The penalty bill, as it passed the Legislature, provides that any person practicising medicine or surgery in that State, without having first obtained a certificate of qualification from one of the authorized Boards of Medical Examiners of the State, shall be guilty of a misdemeanor, and on conviction thereof, shall be fined not less than twenty-five dollars nor more than one hundred.

Summer School of Medicine, University of Virginia.—Several of the teachers and professors of the Medical Department of the University of Virginia have organized, for the coming summer, a private school of medicine, intended as preparatory instruction for those who propose to begin the study of medicine, and for those who are seeking proficiency, especially in the essential groundwork studies of anatomy, histology, chemistry, and physiology.

A Good Suggestion.—"One who hath suffered" gives a hint in the London *Times* which should be remembered by those who have the training of nurses. It is that nurses should be taught that harm is often done when they are attending ladies by telling them dreadful stories of their former patients. It is, however, rather too much to hope that nurses will allow themselves to be deprived of this, the most delightful part of their vocation.—*Hospital Gazette.*

Dartmouth Medical College.—The annual catalogue of this college for 1891, announces that hereafter four years of medical study and three full courses of lectures will be required of candidates for graduation.

Discontent at the Faculty of Medicine at Paris.—Discontent respecting the management of the Faculty at Paris has become so general and so emphatic, that steps have been taken to establish a rival to it, and the Paris Municipal Council has commenced organizing. The medical teaching in Paris has, for many years, been divided into two parts, the professors' lectures, and the Fellows' (agrégés) complementary courses. These latter are the most practical and most popular method of instruction, but, in the interest of the professors, who possess all the official influence, they are neglected and tabooed, and the means of teaching are withheld from them.

Virchow Street.—The German Emperor has ordered that the street at the back of the Friedrichshain Hospital in Berlin shall in future bear the name of Professor Virchow, to whose untiring exertions the hospital in large measure owes its existence.

The German Surgical Congress.—The twentieth annual meeting of the Congress of the German Surgical Society commenced in Berlin on April 1st. The subject of Dr. Koch's treatment for tuberculosis was introduced by Professor von Bergmann, who dealt especially with the effect of tuberculin on local tuberculous affections. The method, he said, was in its infancy, though it opened up a new path the ends of which were as yet veiled even from the prophetic eye of science. He insisted that the utmost care should be taken in the administration of the remedy. Professor König, of Göttingen, spoke favorably of the value of the remedy, though he feared that years might elapse before the best method of using it was thoroughly understood. He also insisted upon the necessity of the most extreme care in its applications.

Good News for the Children.—Owing to the increasing and constant warfare by the National Confectioners' Association, there has been a very marked decline in the number of instances of untoward effects from candy eating.

Medical Legislation in California.—The California Legislature has enacted a law establishing a State Hospital for Inebriates and providing for the legal commitment of this class of persons under much the same conditions as those of the commitment of lunatics. Another good law is one which defines the phrases "incompetent," "mentally incompetent," and "incapable," as meaning any person who, though not insane, is, by reason of old age, disease, weakness of mind, or from any other cause, unable, unassisted, to properly manage and take care of himself or his property, and by reason thereof would be likely to be deceived or imposed upon by artful or designing persons.

Physicians and Life Insurance.—In November, 1888, Dr. George Bernays, of St. Louis, cut his finger while performing a surgical operation. Erysipelas set in, and he died within thirty days. Mrs. Bernays demanded of the United States Mutual Accident Association the sum for which the doctor was insured, claiming that his death was the result of accident. The company admit the cutting, but deny that he was seized with erysipelas then, claiming that he had had the disease nearly all his life. They claim further that as "there was no visible mark on his hand at the time of his death," there is no liability upon them to pay the insurance by reason of a stipulation in the contract or policy. The rulings of the court and the final decree in this case will be of interest to physicians throughout the country, and will have a material effect upon the readiness of physicians to take accident insurance policies.—*Medical News.*

The Ordinary Obstetric Fee in the interior of China, according to a writer in the *Medical Missionary Journal*, is, among the better classes, two dollars when the child proves to be a boy, one dollar for a girl. Among the poorer, one dollar for a boy and fifty cents for a girl.

A New Hospital for the Turks.—One of the largest hospitals in the world, containing accommodations for from 1,000 to 1,500 patients, has been opened at Constantinople, Turkey.

The Canada Lancet thinks that the character of the profession needs to be improved. The immediate cause of this depressive feeling is the startling press notice of a Canadian physician to the effect that "through the personal influence of Lord Stanley, Sir Charles Tupper, Sir John A. Macdonald, The Dominion Government, Lord Salisbury and the Lord High Chancellor of England he has secured a supply of Koch's lymph for use in his '*own*' private practice."

Busy but Constipated.—There is a busy quack in Paris, who, according to the *St. Louis Medical and Surgical Journal*, has hardly time for eating or sleeping, and none whatever for the remainder of human functions, on account of the throng of patients.

The Death of Dr. Joseph H. Warren, of Boston, took place on March 25th. The deceased, who was sixty-five years of age, had devoted much attention to gynecology and to the operative treatment of hernia.

Creasote and Compressed Air.—According to a cablegram medical circles in Paris are greatly interested in a so-called new system of treating tuberculous diseases. According to this method, devised by Professor Germain Sée, patients suffering from tuberculosis pass four or five hours daily in a close chamber, wherein the air is above normal pressure and is saturated with creosote and eucalyptol. The pressure is gradually increased until it reaches a maximum of an atmosphere and a half. Several excellent and permanent results, it is announced, have been obtained.

Suicide of a Physician.—Dr. Arthur Vokes, a physician of Chicago, committed suicide, April 14th, with morphine. His ambition had been to discover a specific for Bright's disease, and after years of unremitting investigation he believed he had succeeded. Within the past few days, however, he was undeceived, and the disappointment appears to have been more than he could bear.

Dr. George Evertson Moore, a physician of this city, died April 15th at his residence, from influenza followed by pericarditis. Dr. Moore was born in 1851 in Ulster County. He graduated with high honors from the College of Physicians and Surgeons in 1878. He at once entered Chambers Street Hospital. After serving there, Dr. Moore went to Europe to pursue his studies, and on his return to this city he started in practice. He became connected with the New York Dispensary as a visiting physician.

A White Flag Over Hospitals.—Dr. Henry C. Cooper suggests that a high flagstaff and a white flag should be attached to all sea-port hospitals and that the flag should be kept floating in times of war.

The French Surgical Congress held its fifth annual session in Paris beginning March 30th, and devoted the most of its early sessions to the surgery of the nervous system. Mr. Boyce, of London, presented the results of English work, and several French surgeons showed that they were not behind in this special branch. A partially successful case of trephining for Jacksonian epilepsy was related (*British Medical Journal*) by Dr. Jeannel, of Toulouse. One case of compression by effusion of blood and one of traumatic epilepsy were mentioned by Dr. Duret, of Lille; trephining had been successful in both, but in the former case the patient was seized with acute cerebral congestion on the twenty-third day, after a drinking bout, and died with convulsions of all his limbs. Dr. Girard, of Grenoble, related a case in which an epileptic woman shot herself in the right temple with a revolver; trephining was performed, the bullet and some chips of bone were removed and the skin wound stitched up, no drainage tube being left in; healing was complete on the seventh day, and for five months the great epileptic crises have ceased, attacks of vertigo have become rare, and consciousness has been lost only once. Menstruation, which formerly was almost constant, is now regular. In fact, the operation which was undertaken for the injury seems to have cured the epilepsy. Dr. Reynier, of Paris, brought forward the case of a girl, aged ten, who was the subject of a cystic tumor situated at the lower extremity of the pre-Rolandic sulcus and extending into the gray matter. M. Charcot having diagnosed "partial sensori-motor epilepsy corresponding to a probable lesion of the middle and lower parts of the Rolandic convolutions," trephining was performed on August 19, 1890, but it was found impossible to remove the whole tumor. A second attempt on December 15th was more successful, and the child is now practically cured, no epileptiform attacks having occurred since December 22d. A case in which a serous cyst of the brain was successfully removed was related by Dr. E. Doyen, of Reims, and another in which a cerebral abscess following a gunshot wound was cured by operation was communicated by Dr. Picqué, of Paris. Dr. A. Broca discussed the general indications for trephining, excluding the immediate effects of injury. Dr. P. Michaux, of Paris, related a case of non-traumatic meningeal hæmorrhage, due to alcoholism or uræmia, which he cured by trephining. M. Lannelongue presented a communication on craniectomy in microcephalus in backward children, and in young subjects presenting various symptoms of cerebral disorder, with or without epileptic crises, based on twenty-five cases, of which twenty-four were "operative-cures;" there was one death from acute septicæmia. As to the definitive results, in a very large proportion of the cases there was improvement both in the intellectual power and in power of walking.

Obituary.

JAMES KINGSLEY THACHER, M.D.,

NEW HAVEN, CONN.

Dr. James Kingsley Thacher, Professor of Physiology at Yale Medical School, died April 20th, of pneumonia, after an illness of two days. Dr. Thacher was born in New Haven, Conn., in 1847. He was a son of the late Professor Thomas A. Thacher, and grandson of President Day of Yale College. He was graduated at Yale in 1868. He became a tutor at Yale in 1871, and at the same time pursued original investigations in comparative anatomy and physiology. The results of these studie were first published in the Transactions of the Connecti cut Academy for 1877, and commanded immediate attention throughout Europe. He maintained that the limbs of higher vertebrates were developed from the fins of fishes. Dr. Thacher was graduated at the Yale Medical School in 1879, and was appointed professor of physiology immediately afterward. He commenced the practice of medicine in 1880, and of late years had charge of the department of clinical medicine at Yale. His services to the hospital have been of the greatest value, and he maintained a position in all respects in the front rank of the medical profession. He had been an active member of the Association of American Physicians ever since it was organized. His investigations in electro-therapeutics in 1885 and in heart action and pulse-wave transmission in 1888 are of the highest merit. He had charge of the medical work in connection with the Century Dictionary in 1878.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 2, 1891.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

A Manure Nuisance.—DR. H. D. CHAPIN, Chairman of the Section on Public Health and Hygiene, said that attention had been called at this Section to a nuisance at the foot of East Forty-sixth Street, in the form of a manure heap, and those who had charge of the transportation of manure from the city were seeking permission from the Board of Health to unbale the manure, separating it from the straw when placed upon the barge in the river. The Section had disapproved of this, as it would in part nullify the benefit derived from placing the manure in bales instead of in open carts as heretofore.

DR. H. E. CRAMPTON offered a resolution to the effect that this action would be deemed by the Academy as injurious to the public health, and that a committee be appointed to urge upon the Board of Health the importance of carrying out the provisions of the law regarding unbaling of manure within the city limits.

DR. HEINEMANN and DR. R. W. TAYLOR opposed the motion, on the ground that the Academy would lose prestige with the public if it were to be constantly passing resolutions concerning individual cases of this kind. The same point was raised later in the evening.

An amendment was passed referring the matter to the Standing Advisory Committee to the Board of Health.

Lupus, with Report of Results Obtained in the Treatment of Lupus by Inoculations with Koch's Tuberculin.—DR. H. G. PIFFARD read the paper. In the first part he reviewed the subject of lupus from an historical standpoint, stating that this was all the more necessary because the name had not always been limited to the same clinical features. The author had taught for fifteen years a common basis for lupus and phthisis. He had gone further in 1877, and stated that lupus was infectious. The doctrine had come to be pretty well accepted that certain cutaneous affections were produced by infection of tubercular material, and were classed under the head tuberculidæ. They included lupus erythematosis, lupus vulgaris, lupus exedens. The latter was generally supposed to belong to epithelioma, but he did not agree with this view, although he believed that there was a closer connection between lupus and epithelioma than was generally supposed. It would be seen that his views of the infectious nature of lupus antedated the discovery of the tubercle bacillus in these cases.

Speaking of treatment, he first described the methods in vogue the past twenty-five years, and concluded by giving the results of the injection method proposed by Koch. Aside from this, the treatment had consisted of some surgical and some local destructive measure, as the use of caustics, cautery, curette, knife. It had been found that, to be efficient, it was necessary to destroy every particle of the disease, every cell which might be capable of reproducing the affection. This fact had been known to clinical observers before they were made acquainted with the bacillus tuberculosis which had since been found in the diseased tissue. Of course the first radical way to suggest itself to the surgeon was excision. This was, however, the best method in only a few cases. The incision should extend at least a quarter of an inch into the surrounding healthy skin in order to avoid a relapse. This precaution was even more important in lupus than in epithelioma, since the former disease branched out more deceptively than the latter.

The actual cautery applied superficially was not to be recommended. Potential cauteries, such as Vienna paste, were reasonably effective, but were painful and liable to do harm. It was true that arsenic seemed to have an affiliation for the diseased tissue, but it did not spread out sufficiently, and was likely to leave diseased cells to favor relapse. Besides, it was exceedingly painful. The simple use of the scoop, or Volkmann's operation, was also objectionable, as not being sufficiently thorough.

The author recommended, about fifteen years ago, a combined operation by the scoop and cautery. The only change which he had to suggest in this mode of treatment was the use of the platinum cautery at a red heat instead of a white heat. During the past year he had been trying scarification and cross scarification by the cautery, making scars in surrounding healthy skin as close together as possible. Further experience would be required to decide whether this method was superior to the use of the scoop and actual cautery alone. The dental burr was of advantage in going down into crypts.

Regarding treatment by injections of tuberculin, it was to be remarked at the outset that Koch had not said this method would cure lupus, nor, for that matter, any other disease. The clinical observations regarding the reaction and general effect of such injections in lupus recorded in Europe had been verified in this country. For a time patients were discharged almost daily from hospitals, reported cured, but they had been treated by those whose experience previously had been almost exclusively with pulmonary tuberculosis and who did not appreciate the deceptive nature of lupus. It was safe to say that few, if any, of these cases had been permanently cured. In most of them the "apple-jelly appearance" was present on their discharge, and where this was so it was to be expected that after a few weeks there would be a return. Cases of this kind were no better off than they probably would have been had they been treated for an equal length of time surgically, for instance by the scoop and cautery. Not until the cicatrix had lost its rosy hue and become blanched could we congratulate ourselves on the permanency of the result. The statement of Koch that local or general reaction indicated, as a rule, bacillary invasion, had been verified. There were, however, exceptions to the rule.

The lymph did produce a decided change in lupus, apparently in the direction of a cure, changes which were not brought about by any other known internal or injected remedy. It must be remembered, however, that an active drug, like a two-edged sword, was potential for evil as well as for good. Tuberculin was not unattended with danger even when used with the ordinary precautions. Three cases of lupus had been reported in which the injections had been followed by death. Theoretically considered, we had in the lymph a remedy whose action seemed unique. Unlike other drugs, whose action was seen in both the physiological and the pathological state, this agent seemed to act only in a certain pathological condition. It was a well-known fact that cutaneous lesions would sometimes disappear in the presence of erythematous diseases. It was not surprising, then, that lupus should sometimes disappear under repeated attacks of pyrexia produced by tuberculin. This was only thrown out as a suggestion, and not as an explanation of the action of tuberculin. It was the author's opinion that, as a rule, surgical procedures would offer better results, obtained with greater safety, than the lymph injections.

Statistics.—The reader referred to the recent official report of results of treatment by tuberculin in the Prussian hospitals, and said that of two hundred and fifteen cases of lupus only five were said to have been cured. In thirty-eight trial cases in Paris, not one had been cured.

Cases Treated at Mt. Sinai Hospital. — DR. H. N. HEINEMAN gave the results of treatment of nine cases of lupus with tuberculin, most of which had been seen at the Mt. Sinai Hospital. In his preliminary remarks he cautioned those who intended to try the method not to use large initial doses. For instance, it had been said that in some cases of lupus an initial dose of ten milligrammes might be given, but it was much safer to begin with the usual minimum dose and gradually work up. In one of

his cases a dose of three milligrammes had produced such reaction that he sat up with the patient all night to make sure that he would not slip away. The treatment in most of his nine cases had been begun four or five months ago. The duration of the disease had varied from three to fifty years. In one case, when the dose was increased, it seemed to cause rapid spread of the disease, but on reducing it again to three milligrammes healing took place. In most cases there had been more or less improvement apparent, but of only one could it be said that there had been all but a complete cure. He had no doubt but what a quicker and more complete result would be obtained by combining local and tuberculin treatment. This course was being pursued abroad.

Cases Treated in Bellevue Hospital.—Dr. H. P. Loomis illustrated, with lantern slides made from negatives by Dr. Fuller, cases of lupus treated by tuberculin in Bellevue. The cases described were four in number. In most the change had not been great. In an old woman, who had infiltration of the face and a few apparent ulcers, and also a large epithelioma below the cheek-bone, the thickening and infiltration over the entire face and the small ulcers disappeared, but no effect was produced upon the epithelioma. The injections were continued until they ceased to produce any general or local reaction.

The Tubercular Origin of Lupus Sub Judice.—Dr. R. W. Taylor said that while it would seem the theory of the bacillary origin of lupus was the correct one, yet it was not so generally believed in as the author thought. We were not yet in a position to speak of the mode of implantation of the bacillus, its mode of propagation in the skin, and the appearance presented by it in newly infiltrated areas. Within the last few years other affections had been regarded as allied to lupus (the classical description of this disease), upon the supposition that it was of tubercular nature. Perhaps it was, but the fact had not been clearly made out. The opinion which had been expressed, that most cases of tuberculous skin were associated with tuberculosis of the lungs, was in direct opposition to the observations of others. In how many cases of lupus did one find associated pulmonary disease?

He agreed in the treatment recommended by Dr. Piffard, but thought that caustics would in many cases be more efficient and more easily handled than the actual cautery.

The Knife Contraindicated.—Dr. G. H. Fox, speaking of the treatment of lupus vulgaris, said he had never seen a case, either limited or extensive, in which the curette or some other method was not better and more agreeable to the patient than the knife. He did not approve of the galvano-cautery, claiming that it necessitated the destruction of too much healthy tissue in order to get rid of all the disease. He preferred caustics, especially in connection with the curette. He favored the action of a weak caustic, as pyrogallic acid, which kept up a suppuration, to more active caustics which left a slough. Linear scarification was desirable in some cases of lupus of the nose. The dental burr was invaluable for the cure of some of the underlying small ulcers with a wide base.

Regarding Koch's lymph, while it had not fulfilled first expectations, yet he thought it would prove of considerable value, especially in connection with other forms of treatment in cases which proved rebellious to surgical measures alone.

Favors Local Measures.—Dr. Prince A. Morrow said that, in common with most dermatologists, he had come to accept the view that lupus was a local tuberculosis. It was worthy of note, however, that many dermatologists by no means subscribed to this view. Some did not recognize the bacillus of Koch as the pyogenic agent.

With regard to tuberculin, he thought Dr. Piffard had done well to compare this method of treatment with those of a local destructive nature. He had had opportunity to examine a number of cases subjected to the Koch treatment. Certainly the results in some were most striking. At the same time he did not think that dermatologists who were familiar with the chronic, the almost intractable nature of this affection, with its tendency to recur, would be disposed to accept the statement that by the injection of a lymph into the system the tuberculous tissue would be attacked and destroyed, and a cure be effected in the brief period of a few weeks. This claim was regarded as premature, and had been received from the first with very marked incredulity on the part of most dermatologists. It was thought that six to eighteen months would be necessary to decide upon the cure of the disease. It had been found that the majority of the cases which had been reported as brilliant cures showed, within a short time, signs of relapse, and in some cases new foci of disease developed, and in some the condition was worse than when the treatment was begun. The Prussian and Parisian hospital reports were quoted.

Another Unfavorable Opinion of Tuberculin.—Dr. Edward B. Bronson had had under observation a few cases of lupus treated by injection of tuberculin, and the impression which the mode of treatment had made upon his mind had been unfavorable. One case was apparently progressing toward a cure when the patient left the hospital. In most of the cases, however, although there had been temporary improvement, the ultimate result had been very unsatisfactory. In one case, treated three months, there had been no result whatever. In general, time spent in making the injections seemed to be time lost. A much more satisfactory result would have been obtained by surgical procedures.

Referring to Dr. Fox's suggestion, to keep up a low form of suppuration, he expressed the opinion that it was contrary to good surgery, and said he preferred to effect a cure as soon as possible. It seemed to him that suppuration was a thing which ought to be avoided.

Dr. Piffard closed the discussion. He said it was true that in the beginning lupus seldom showed associated lung trouble, but if the cases were allowed to go on they were likely to ultimately kill the patient by phthisis or epithelioma. Nor were we likely in cases in which tuberculosis of the lungs had existed for some time to find lupus, for the reason that the bacilli had found a better place than the skin. He had had a case of lupus in a woman, in whom it had developed two years after her marriage to a man who had tuberculosis of the lungs.

Public Baths.—Dr. Simon Baruch read a brief paper on public baths. He said that that portion of the community which had the greatest need of bathing had the least facilities for it. Clerks, mechanics, laborers, and their families, ought at least to have as good opportunities for keeping the skin clean as wealthy people thought was imperative for the health of their horses and other animals. The so-called tenement-house odor, which offended the nostrils of cleanly people in public conveyances, emanated from decomposed secretions of the skin which accumulated upon the body of uncleanly people and in their clothing. It was not only a moral obligation upon the community, but a necessity for the safety of their households, to remove this evil. Above all was it the duty of the city authorities to do so. He would advise the adoption of a method whose simplicity and cheapness should overcome every objection. Its essential principle was the abolition of the tub and the substitution of the rain or shower bath. The bather sat upon an inclined plane, drew upon a chain, and a shower of tepid or cold water poured upon him while he scrubbed himself; the soiled water flowed away. The advantages over the tub were, saving of first cost and wear; saving of labor; saving of time, thus accommodating more bathers; economy of space; less danger of communicating disease, etc.

Following the reading of the paper Dr. Crampton offered the following: "Resolved, That the New York Academy of Medicine approves of the construction of public baths in this city as a sanitary measure of the highest importance."

As in the first part of the evening, several of the members objected to the Academy adopting resolutions relat-

ing to special matters as likely to lower its dignity and lessen its influence with the public. They thought such matters could be referred to a standing committee. The majority, however, were not of this opinion, sixteen recording their votes in favor of the resolution, eleven against.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 25. 1891.

H. M. Biggs, M.D., President, in the Chair.

Dr. John H. Linsley said that, in view of the great interest taken in Koch's treatment of tuberculosis, he wished to refer to a letter he had just received from Professor Carl Fraenkel, who, as is well known, is intimately acquainted with Professor Koch. In this letter, which was written as an introduction to Dr. Linsley's translation of Fraenkel's book on Bacteriology, Professor Fraenkel refuses to discuss the present status of this new treatment, on the ground that at the present time experiments were still in progress, and the success of the method seemed very doubtful.

Single Kidney, with Acute Interstitial Nephritis, and Colloid Carcinoma in the Bladder.—Dr. H. S. Stearns presented a report of such a case. The subject of the report was a German shoemaker, fifty-two years of age, who was admitted to the Charity Hospital on January 9, 1891, with a history of considerable pain in the hypogastrium and right iliac region for five weeks, and of retention of urine for two days. The catheter evacuated considerable pus, but not much urine. On the following day the lungs became œdematous, and he died within twenty-four hours. At the autopsy, thirty-two hours after death, the lungs and heart were found normal, with the exception of the pulmonary œdema. The liver was slightly fatty. The only lesion of the intestines was an intense hyperæmia of the peritoneal surface of the cæcum, but no adhesions or anything abnormal were found on the internal surface. The cavity of the bladder was only 4 ctm. in diameter and was partly filled with pus. There were two polypoid masses, each about 1.5 ctm. in diameter, projecting into the viscus, which proved to be carcinoma with colloid degeneration. The wall of the bladder was greatly hypertrophied, and beneath the larger of the two malignant growths it had almost ulcerated through. The left kidney was absent. The right kidney was very large, weighing, with its capsule, 27 ounces. The capsule was 5 ctm. thick and was non-adherent. In stripping off this thick capsule, small abscesses were found between it and the kidney. Microscopical examination showed in the cortex round-cell infiltration about many of the glomeruli and convoluted tubes. Round cells were seen thickly packed in a few tubules. Degeneration of the epithelium was almost universal. Here and there were seen areas of colloid degeneration, but nothing that could be positively asserted to be carcinomatous. As regards the elements of the cortex, the glomeruli and tubules seemed somewhat larger than where both kidneys are present. The pelvis of the kidney showed no evidence of inflammation. The ureter was quite large, but otherwise apparently normal.

The President remarked that cases of colloid cancer of the bladder must be very rare, as in a somewhat extended search which he had recently made into the literature he did not recall a single recorded case.

Sarcoma of the Knee.—Dr. R. H. Sayre presented a specimen which had been removed a few days before by amputation of the thigh. The history dated back three years, and began with pains in various joints, occurring shortly after the patient's confinement. One year later, after falling downstairs, there was an acute inflammation of the knee, which was thought by the attending physician to be an ordinary synovitis. The case was treated by massage, but was not improved. About sixteen months ago, the speaker's brother had seen the patient, and had found a knee-joint which resembled that ordinarily seen in simple tubercular disease, except that there was more swelling of the lower end of the femur. An extension splint gave much relief, and the size of the knee was reduced two inches by strapping. The case had been under the care of the speaker for about a year, during which time it had been treated by extension and immobilization. There had been a morning temperature of 99° F., and an evening one of 100° F., and the patient had had occasional chills. There was supposed to be extensive bone disease, and an operation was advised, but not insisted upon, as the long duration, the irregular temperature, the general condition of the patient, as well as the local appearances, did not point toward malignant trouble. After making the flaps for an amputation, the limb suddenly dropped off, and it was found that the shaft of the femur was very extensively diseased, and the joint was filled with a giant-cell sarcoma. The inguinal glands were slightly enlarged, but no other secondary nodules were found, and nothing to indicate such deposits in the internal organs. The history was rather indefinite as to the exact point at which the trouble began, but it probably began as an active inflammation in the tibia.

Dr. H. J. Boldt asked if it were not probable that the disease was benign at the beginning, but subsequently became malignant as a result of the long-continued irritation.

The President said that sarcomata of bone most frequently began in the upper end of the tibia, and next in frequency in the femur. The specimen showed a very typical giant-cell sarcoma, and from its appearance he thought it had probably begun in the tibia.

A Remarkable Case of Slow Gangrene.—Dr. Eugene Hodenpyl presented specimens from a case which had, for upward of twenty years, puzzled and interested a number of physicians. When about forty-five years of age, and apparently in good health, gangrene developed in one big toe, which was amputated. Following this, gangrene successively attacked the other toes, and then the lower extremities, so that in all, about twenty amputations were performed. A very careful investigation by the physicians failed to elicit any history or evidence of syphilis, diabetes, or similar disorders. In January of 1890, the end of the penis becoming gangrenous, amputation was performed. He remained in good health up to five days ago, when he was seized with vomiting, and then with an ill-defined pain in the epigastrium, which gradually extended over the abdomen. On admission to the hospital at this time the temperature was found to be normal, and no other symptoms were present for several days, when he suddenly went into collapse and died. At the autopsy, on opening the abdomen, it was found filled with blood. The lungs showed the pneumonia of heart disease. The heart was found to be somewhat enlarged, and the cavity of the left ventricle was dilated and its walls hypertrophied; there was also some thickening of the myocardium and of the aortic and mitral valves. The first part of the aorta was nearly normal, but at the arch were several soft atheromatous spots, and at the commencement of the descending aorta was a large nodule. The atheroma extended down the aorta to just above the origin of the common iliacs, where numerous large and small ulcerations were found. This portion of the aorta was very soft and spongy, and it was evident that the hemorrhage took place here, for the subjacent tissues were infiltrated with blood. The spleen, which was very firmly adherent to the surrounding tissues, weighed one-and-three-quarter pounds. It was very hard, irregularly and coarsely nodular, and on section showed several very large, characteristic gummy masses. In fact, nearly the whole spleen was converted into gummata. The kidneys showed the ordinary lesions of chronic diffuse nephritis, and explained the condition of the heart. The liver, stomach, and intestines were nor-

mal. Permission could not be obtained to examine the brain. The gangrene was evidently due to thrombi in the aorta.

Microscopical Examination. — Sections through the spleen showed that the gummata were converted largely into dense, almost structureless, cheesy material. The cheesy areas were surrounded by a zone of small spheroidal cells, which were in turn enclosed by dense fibrous tissue. There was extreme atrophy of the remaining spleen pulp. Sections through the wall of the aorta showed the ordinary appearances of atheroma in various stages. At the lower end of the aorta, where the rupture is supposed to have taken place, the ulcers were large, numerous, and often deep, extending in places almost through the wall of the artery. The tissue surrounding the ulcers was infiltrated with small spheroidal cells, and seemed to be partially broken down.

Dr. E. Fisher referred to a very similar case which had come under his observation, in which the gangrene involved first one foot and then the other, becoming symmetrical. The disease extended beyond the limits found in Reynaud's disease, and finally necessitated amputation of the knee. No reason could be found for this condition during life, but the autopsy revealed a very similar state of affairs to that which had just been described.

Ulcer of the Duodenum.—The President presented specimens of this rather rare condition. They had been removed from a woman, who could give no previous history except that she had some chilly sensations and obstinate vomiting with abdominal pain for some time previous to her admission to the hospital, which was on January 19th. At that time she was stupid and deeply jaundiced. The temperature was irregular, reaching at times 104.5° F., but ranging most of the time between 101° and 102°. She remained stupid for the most part, but occasionally became delirious. Severe vomiting occurred at intervals. She complained of pain on the right side near the free border of the ribs, and an examination of this situation showed the presence of a hard tumor. Two diagnoses were made, viz., one of gall-stones, the other of carcinoma of the stomach, or of the gall-bladder and duct. Death occurred from asthenia.

At the autopsy, the lungs, heart, and all the organs except the duodenum and liver were bile-stained, but otherwise normal. In the descending portion of the duodenum, and involving almost its entire circumference, was a large ulcer with elevated and indurated borders, situated just beneath the papilla marking the termination of the gall-duct. The gall-bladder was much dilated, and on pressure this papilla became swollen and elevated, and thin bile passed through. The tumor was due to dilatation and thickening of the gall-duct. The liver was very intensely bile-stained and somewhat fatty.

Apparently in the early stages this ulcer had almost completely occluded the bile duct, giving rise to obstructive jaundice and dilatation of the gall-duct, but later on the duct had again become pervious. These cases of ulcer of the duodenum were not common and the clinical history was always obscure. In some instances there were scarcely any symptoms, and he had never known of the diagnosis of ulceration of the duodenum which had been confirmed by autopsy. He had seen a case of sudden death in a sailor who was apparently in perfect health, yet the autopsy revealed peritonitis from perforation of the duodenum at the site of an old ulcer.

The Society then went into executive session.

Drunkenness in Edinburgh is not a punishable offence. Persons found in this state are arrested for their own protection and released upon recovery. In this country the punishment of inebriates as criminals is thought to check inebriety. The practical result is that the inebriate is educated into a criminal and becomes a dead weight on the community.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

SOME CHEMICAL POINTS IN THE TREATMENT OF DIABETES —THE INDIAN OPIUM TRAFFIC—HETERALOPIA OF THE SPINAL CORD—INTESTINAL STRICTURE SECONDARY TO STRANGULATION IN A HERNIAL SAC—THICKENING OF SKULL FROM RICKETS—CHRONIC ATROPHIC RHINITIS CURED BY INOCULATION WITH GONORRHŒAL PUS.

London, April 11, 1891.

Some interesting and novel points in connection with the pathology and treatment of diabetes were brought forward by Dr. A. E. Wright, late Research Scholar of the Grocers' Company, in a lecture recently delivered at the University of London. The lecturer pointed out that all sugars were not alike in their effect on the diabetic organism. Professor Külz had succeeded in establishing that levulose differed from dextrose in this respect. The chemistry of the sugars thus became of importance to the physician. Dr. Wright presented the following classification: I. Monosaccharids: Dextrose, levulose, galactose. II. Disaccharids: Milk-sugar (composed of dextrose and galactose), Cane-sugar (composed of dextrose and levulose), Maltose (wholly composed of dextrose), III. Polysaccharids: Dextrose group (starches, dextrins); levulose group (inulin, levulin). Of these, dextrose, starches, and dextrins were unassimilable hurtful sugars; levulose, inulin, and levulin were assimilable innocuous sugars; galactose had not yet been sufficiently studied.

The lecturer observed that there was at present a universal consensus of opinion among clinicians that the carbohydrates in the food of the diabetic patient must be restricted in order to avoid poisoning the system by the presence of large quantities of unassimilable sugar; some clinicians absolutely prohibited all carbohydrate food. Such absolute restriction had not, however, always resulted in unmixed good. It had been shown that, although the sugar was thus reduced to a minimum, other morbid products, such as acetone and oxybutyric acid, appeared or increased in quantity in the urine. The ideal diet for a diabetic would be one consisting of proteids and fats, to which the innocuous lævo rotatory carbohydrates had been added in such quantities as were available, or, in default of these, the "assimilable quantum" of dextrorotatory carbohydrates, at least whenever the bad results of a proteid diet were manifesting themselves. The importance of the fats in the diabetic dietary had not been sufficiently emphasized in this country.

Of the entirely assimilable class of sugars we had only two—levulose, and inulin. The former did not occur by itself in nature. Inulin was a homologue of starch, with the important difference that, instead of yielding dextrorotatory simple sugars, as starch did, it yielded only lævorotatory simple sugars. It occurred abundantly in dahlia tubers, in dandelion, chicory, and other roots, and it could be baked into a good bread. Against it was its price, some fifteen shillings per pound; if it were cheaper, the first step would have been taken toward its being produced for the market; at present, an innocuous sugar for dietetic purposes remained an unrealized desideratum, though we might possibly have an approach to such a food stuff in the Jerusalem artichoke, the carbohydrates of which, according to Tollens, were levulin and inulin during the spring and summer, while dextro-rotatory carbohydrates made their appearance, in the tubers only, in the autumn.

As we were not able to give the best thing in the way of carbohydrates to our patients, we had in certain cases to inquire what was the next to best, viz., the "assimilable quantum" of dextro-rotatory carbohydrate. The lecturer remarked that he had used the term "assimilable quantum" as if every diabetic had an appreciable quantity of dextrose he could assimilate without secreting

sugar. This obviously could not be the case in the severe form of diabetes, in which the patient continued to excrete sugar even although he might be taking none. But, on the other hand, there was reason to believe that no diabetic patient, even of the severe form, excreted all the sugar he took in his food. He was, in fact, in almost exactly the same position with regard to sugar excretion that the diabetic of the lighter form was when he had been given sugar in excess of his assimilable quantum. With reference to the question of giving carbohydrates in the severe form of diabetes, Dr. Wright suggested that something might be ventured in that direction so long as the assimilation ratio was moderately high, and so long as what he had called the morbid products of proteid metabolism were urgently requiring attention. But it was only when there was urgency of this kind that an increase of sugar in the urine should be permitted, and in other cases it was only a weak pity that would allow a diabetic unnecessary carbohydrate.

The lecturer said we had no knowledge of what he had from the clinical stand-point called a mixed sugar in the chemical class of the non-crystallizable polysaccharids. They either fall entirely within the class of assimilable or of hurtful sugars. When, however, we came to the group of the disaccharids, we met with two examples of mixed sugars, viz., cane-sugar and milk-sugar. From its chemical constitution it resulted that two parts by weight of cane-sugar contained less unassimilable sugar than one part by weight of starch. This meant that we might allow fruit in diabetes a great deal more readily than we might allow bread, and it showed that in the selection of vegetables for the diabetic patient we should choose such as contained as much of their carbohydrates as possible in the form of cane-sugar. With regard specially to such fruits as grapes, the sugar of which was almost entirely cane-sugar, it was wonderful how little harm resulted to diabetic patients from eating great quantities of them.

Milk-sugar consisted of equal parts by weight of dextrose and galactose. If galactose were an assimilable sugar—a point not yet made out—milk-sugar would also fall into the category of the mixed sugars. There were considerable difficulties in the way of ascertaining whether galactose was assimilated or not, and it was plain that the question could not be settled without a large number of observations. The general result of those made on man was that the addition of milk-sugar to a diabetic diet, in almost all cases, seriously increased the amount of sugar in the urine; this should obviously be expected, seeing that it contained fifty per cent. of dextrose. When we came to the practical clinical side of the matter we found that milk, because of the four per cent. of milk-sugar it contained, had been steadily forbidden to the diabetic by the great majority of clinicians. Dr. Donkin's "skim-milk" treatment had a good deal to recommend it in the fact that the proportion of fat to proteid was larger than it would be in almost any other diet, but the weak point of it was that the carbohydrate of milk was milk-sugar, which was not a desirable element in diabetic diet. When, however, we came to consider the very severe restrictions that had to be imposed on the diabetic in the matter of diet we could not help feeling some amount of regret in having to proscribe the valuable proteid and fat of milk because of the presence of the milk-sugar. The lecturer said he had been able to arrive at a solution of the problem. Instead of getting rid of the sugar from the proteid and fat of the milk, which he failed in doing, it was evi dently possible to perform the reverse process, and to separate the proteid and fat of the milk from the sugar, *i.e.*, to precipitate the casein and fat of the milk by very dilute acetic acid, filter them off, allowing all the sugar to run away from them, and then to redissolve the washed precipitate in a solution of the normal salts of milk, to which a little alkali had been added.

The indications on the occurrence of which it might be desirable to allow sugar in diabetes were the appearance in large quantities in the urine of the morbid products of proteid metabolism. Among such products were acetone, acet-acetic acid, and oxybutyric acid. With regard to the conditions of excretion of every one of these bodies, a number of facts had been collected which raised a very strong presumption that these bodies had their source in the proteid metabolism of the body. The idea that the administration of alkalies in diabetes was a good routine practice was undoubtedly incorrect, for disappointment generally resulted.

The remainder of the lecture was almost entirely devoted to a discussion of the phenomena of phloridzin-, and phloretin-diabetes.

The question of the Indian opium traffic came before the House of Commons again yesterday evening, when Sir J. Pease's resolution that the system was morally indefensible, was carried by a majority of thirty votes. This was the more noticeable inasmuch as, so far as the speeches went, the proposer of the resolution received but scant support, most of the speakers defending the system. In face of the hostile vote, possibly the Government may propose some modification of the present system.

Two specimens from cases of "heteratopia" of the spinal cord were presented to the Pathological Society at its last meeting. One specimen was from a patient who had for many years suffered from a gradually increasing exfoliative dermatitis, and who, two years before his death, developed severe polyarthritis, which was followed by the signs of a transverse myelitis; death resulted at the age of twenty-nine from exhaustion, due to repeated attacks of bronchitis and the formation of a bedsore. The other specimen was from the body of a man who died, aged twenty-four, from general paralysis of the insane.

At the same meeting of the Society, Dr. Newton Pitt showed a specimen of chronic intestinal stricture, secondary to strangulation in a hernial sac; he said he had only been able to find two cases recorded. Mr. Shattock showed two infants' skulls greatly thickened by rickets.

In the course of a discussion at the Medical Society on chronic atrophic rhinitis, following the reading of a paper by Dr. De Havilland Hall, Mr. Spencer Watson mentioned a case of the disease which had got well after accidental infection by gonorrhœal pus.

SEXUAL INSTRUCTIONS FOR THE YOUNG.

To the Editor of the Medical Record.

Sir: The sexual instinct is the strongest and the ruling passion of the human race—it has always been so and always will be. Though many believe man would be a superior being were he created by some other God-given function, the fact remains that man is as he is, and must evolve from his condition the best possible man.

As man is created, the sexual instinct is the root and foundation of most that is good and most that is bad. The political economist can trace most of the social distress of to-day to abuse of the sexual instinct; the physician can trace most of the physical suffering of to-day to the same cause. Much of this suffering can be avoided by proper training. Possibly, in the distant future, the human race will be intelligent enough to believe that it is a social crime for weakness and disease to beget offspring; possibly then they may show by their deeds that they realize the breeding of humanity is governed by the same laws as the breeding of cattle. To day, however, the laws of heredity are entirely ignored, and disease and weakness are allowed to produce like qualities *ad libitum*, resulting in endless suffering from that stern law, "the survival of the fittest." Could the results of the abuse of this law be truthfully painted, the sight would cause humanity to shudder with horror, and everywhere people would debate as to how these terrible crimes against society could be stopped at once.

Everywhere, to-day, children are born with disease who

could justly curse their parents for their birth. Everywhere, to-day, children are born with health, who from sexual ignorance are destined to acquire and beget disease. The remedy is proper physical instruction — instruction which will plainly teach that children have a right to demand sound bodies as well as trained minds—instruction which will be "sexual," plainly showing that disease produces disease.

The old saying, "mens sana in corpore sano," expresses so much that thus far we have not reached the "in sano corpore." I should change the quotation to read, "corpus sanum in sana mente," and, for a change, train the coming parents to realize that a "corpus sanum" is given by them, a "sana mens" is acquired readily by their children, especially if blessed with inherited sound bodies. From the beginning of man the greatest social forces have been self-preservation and reproduction; or, in other words, what to-day may be called "mental training and sexual training;" thus far sexual training has been left to "instinct," blind instinct, with no reason and no self-control, resulting in venereal disease and hereditary weaknesses, much of which can be avoided by proper and necessary instruction. People yearn, absolutely yearn, for just this kind of instruction, but those who can and should give it cry "'Sh!!" and crawl into their shells when the subject is mentioned. Meanwhile our youth receive instruction from their companions—instruction filled with ignorance and filth, and never touching the great yet simple law that "like begets like," "disease produces disease."

As a teacher of young men I have often overheard "sexual discussions" where an older boy fills his younger hearers with such statements as "clap is not as bad as a cold," and "pox isn't so bad;" but never have I heard one word of good intelligent advice. We know these are true statements, yet we—intelligent parents—take no steps to remedy the evil.

In a crowded room of a boarding-school I have heard a boy of nineteen proudly telling innocent young lads of the location of houses of ill-fame in New York—young lads who should have been kept at home and truthfully instructed rather than be "posted" by such instruction.

I have been in a school attended by noble young lads, and have seen one foul boy contaminate an innocent school—ay! because parents hesitate to instruct in what so closely concerns the welfare of their children. What a satire it is upon the intelligence of "posted" men who remember the days of their youth—days of sexual curiosity and ignorance—that children are forced to be sexually trained by foul and ignorant companions.

We who have mingled much among young boys know how keen is their desire for facts; we have seen it in their anxious faces and in their eager questions—questions which prove that they instinctively believe they should know these things. Should they not? Then let them be instructed carefully and correctly; let them be taught the value of a sound body in the battle for life and social position; let them be taught the use and abuse of the sexual function; let them be taught the stern yet kind laws of heredity; let them be posted correctly, for "posted" in some way they will be.

The silence of the profession upon this subject has long been a mystery to me; daily we see weakness and disease produce the like; daily we see children born but to suffer and die; daily we see venereal disease acquired through ignorance; daily we see ruin and suffering and death, much of which could be avoided by proper training—training which would in itself suppress quack lectures and pamphlets and ignorant "discussions," and substitute in their place truth.

Youth, to-day, bright and curious, knocks at the door of our profession for instruction. They should receive it, and we alone can properly give it. For this reason I have sought the columns of the MEDICAL RECORD, hoping that its host of earnest observing men will seriously consider how sexual instruction can best be imparted. Many favor compulsory lectures, few in number and lasting for several years—the years in which youth should change from animals to "posted" men of self-control—the years from fifteen to eighteen—where without this instruction in many cases the growth is from young animals to corrupt and ignorant men—animals still. In the name of our children and our children's children, in the name of health and purity and perfect manhood, I beg of my readers, filled with the memory of the temptations and ignorance of their young manhood, to see to it that the light of intelligence is cast upon that ignorance which now unnecessarily causes unlimited suffering, disease, and death.

R. ELLIS, M.D.

DANBURY, CONN.

New Instruments.

A NEW ARTERY FORCEPS.[1]

BY A. M. PHELPS, M.D.,

NEW YORK.

SOME of the serious objections to the artery forceps in general use are: 1. The difficulty of clamping an artery in dense inflammatory or fibrous tissue. 2. The tying of the ligature around the forceps instead of the artery. To avoid this in the ordinary forceps the assistant tilts up the end while the operator ties. 3. Arteries clamped in deep wounds are with difficulty ligated, owing to the almost certain tying of the ligature around jaws of forceps.

To obviate these defects Bergman, of Berlin, advised the forceps which bears his name.

FIG. 1.

Fig. 1 furnishes a correct idea of the instrument. It is made of German silver. The jaws are armed with fine teeth or serrations which will grasp and hold hard fibrous or inflammatory tissue. It has a blunt rounded point over which a ligature will always slip. It is clasped with a thumb slide. The objections to this forceps are: 1. Its great weight unfits it for work in cellular tissue or in small operations, when many forceps need to be applied during the operation. So much timber is in the way of the operator, and its great weight tears the tissues away. 2. The slide catch is objectionable, for when the hands are covered with blood it is with difficulty that the slide can be moved to clasp the forceps.

To overcome the objections in the Bergman forceps I devised the forceps figured in Fig. 2.

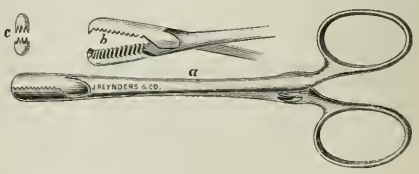

FIG. 2.

They have the jaws of the Bergman, a modified hinge of the French, and the clasp of the ordinary forceps. These forceps will catch dense tissue and hold. They are suitable for operating in deep wounds, because the operator cannot tie on to them, and they are as light as the lightest forceps. There is a forceps in the market simi-

[1] Presented at the Surgical Section of the Academy of Medicine, April 13, 1891.

lar, but it differs in not having the wide blades, which prevents the possibility of tying on to them.

A half-dozen pairs of these forceps, together with other forceps, will be found of great service in certain operations.

40 West Thirty-fourth Street.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 12, 1891, to April 18, 1891.

Birmingham, Henry P., Captain and Assistant Surgeon. By direction of the Acting Secretary of War, the leave of absence granted in S. O. 39, March 13, 1891, Department of the Columbia, is extended one month. S. O. 81, par. 2, Headquarters of the Army, A. G. O., Washington, D. C., April 10, 1891.

Middleton, Passmore, Major and Surgeon. By direction of the Acting Secretary of War, is granted leave of absence for six months, on surgeon's certificate of disability. S. O. 81, par. 4, Headquarters of the Army, A. G. O., Washington, D. C., April 10, 1891.

By direction of the Secretary of War, a board of medical officers to consist of Major Henry McElderry, Surgeon; Captain James C. Merrill, Assistant Surgeon; Captain W. Fitzhugh Carter, Assistant Surgeon, is appointed to meet at West Point, N. Y., May 1, 1891, or as soon thereafter as practicable, to examine such cadets of the United States Military Academy as have been granted leave of absence until that date on account of physical disability, and to report upon their physical fitness to continue with the Corps of Cadets. S. O 83, par. 2, A. G. O., Washington, D. C., April 13, 1891.

Wood, Marshall W., Captain and Assistant Surgeon. By direction of the Secretary of War, is relieved from duty at Fort Meade, S. D., and will report in person to the commanding officer at Fort Preble, Me., for duty at that post, relieving Captain William B. Davis, Assistant Surgeon. S. O. 85, par. 11, A. G. O., Washington, D. C., April 15, 1891.

Davis, William B., Captain and Assistant Surgeon. By direction of the Secretary of War, on being relieved by Captain Wood will report in person to the commanding officer at Fort Clark, Tex., for duty at that station. S. O. 85, par. 11, A. G. O., Washington, D. C., April 15, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 18, 1891.

Beardsley, Grove S., Medical Director. Appointed a delegate to represent the Medical Department of the Navy at the meeting of the American Medical Association, at Washington, D. C., May 5th.

Flint, James M., Surgeon. Appointed a delegate to represent the Medical Department of the Navy at the meeting of the American Medical Association, at Washington, D. C., May 5th.

Griffith, S. H., Passed Assistant Surgeon. Detached from the Dolphin, and granted one month's leave of absence from date of detachment.

The Insanitary White House.—The plumbing inspector of Washington has recently made an examination of the White House, and reports that the condition of the plumbing there is very far from perfect, and recommends a thorough overhauling of the bath-rooms and water-closets.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 18, 1891.

	Cases.	Deaths.
Typhus fever	1	0
Typhoid fever	7	3
Scarlet fever	200	37
Cerebro-spinal meningitis	3	5
Measles	327	23
Diphtheria	108	38
Small-pox	2	0
Varicella	13	0
Pertussis	2	11
Erysipelas	0	0
Mumps	0	0
Rötheln	0	0

What is an Item?—A correspondent writes to inquire what we mean by "items" as a heading for one department of this journal. He says he finds a prescription at one time, a practical hint on diagnosis at another, again a bit of humor, a scrap of news, indeed almost anything that is interesting and yet expressed briefly, all in this one column. An item may be defined as a paragraph, but if that is not satisfactory to our friend we will quote a recent writer in the *Australasian Critic*, who says that the sonnet has been found to be just the proper length for the expression of a single thought in verse, and that the true paragraph may be defined as the sonnet of newspaper prose. We may say, therefore, that our "items" are the sonnets of medical literature.

The Treatment of Chronic Tropical Diarrhœa.—In a paper read before the Medico-Chirurgical Society of Edinburgh, in April, 1890. Dr. Charles Begg stated that he had found santonine the most effective remedy for this disease. His plan of treatment is as follows: He places the patient in bed, or at least keeps him on the couch, and commences the treatment, if a flatulent condition indicates it, by a dose of castor-oil guarded with laudanum. Warm water enemata and hot fomentations are also often employed. The diet is principally milk, eggs, beef-tea, dry toast, or soda crackers, and brandy. The nourishment should be taken frequently in small quantities. Each night a dose of five grains of yellow santonine well mixed in a teaspoonful of olive-oil is given, or, if the patient does not suffer much from the effects of the drug, it may be given the first thing in the morning. This is continued for six days, at the end of which time, according to Dr. Begg's experience, a cure has usually been obtained.—*Edinburgh Medical Journal*, September, 1890.

The Profession in Chicago.—The *North American Practitioner*, published in Chicago, is not altogether pleased with the doctors of the windy city, if the following editorial comment is seriously intended: "One of our friends remarks on the importance and authority of medical students in Chicago colleges. He is astonished that professors recognize them on the street. In those centres of culture and refinement from which all good things emanate, a student is stuff—a mere clod. There is a recompense in all things, and we wish now to assure the medical student that if he remains in Chicago after he graduates he will find that he must come down from his high position and become, so far as his seniors are concerned, mere stuff. They will take his cases from him when they are called in consultation. They will make calls at his next-door neighbor's at two dollars a visit and underbid him for the work of street railway companies, factories, ice companies, and other corporations. They will sit in their offices and write prescriptions at a dollar a piece when they could do better work, make more

money, and be a credit to the profession at five times these fees. The student will, after years of experience of this kind, wish he had been treated as a clod during his short years of study. This Cheap John sort of business is encouraged by the lawyers, who go about and secure expert testimony for their clients from the lowest bidders. In a case involving many thousand dollars, a physician was consulted and requested to give an opinion, and be ready to testify in court. For so simple a proceeding as the examination of a crushed elbow, he, an untitled doctor, had the presumption to charge fifty dollars. At this the legal light rebelled and cited as a precedent the fact that he had two professors of surgery for expert testimony at ten dollars apiece. We can only explain such a dog-in-the-manger policy on supposition of a *furor* for advertisement. The fees of Chicago physicians of well-established reputation are niggardly. This class of men monopolize the hospitals without time to utilize them for scientific purposes, because they are too busy picking up their petty fees to observe, to read, and to investigate. Therefore our societies are barren, our schools mercenary and homely, our hospitals priest-ridden and mismanaged, and the profession undistinguished abroad and unrespected at home."

Insomnia in Infants.—Dr. Jules Simon considers insomnia a symptom of much importance in infants. In many diseases it is a symptom of minor importance, and of no special interest. In others it is one of the chief manifestations of the disease. The influence of dentition has been greatly exaggerated. Unless congestion of the gums or surrounding parts is present, it causes but little disturbance of the sleep. Dyspepsia and indigestion are the most common and universal causes of disturbed sleep, even without the definite symptoms of vomiting, diarrhœa, or marked constipation. A discussion of the treatment would involve a review of the whole subject of dietetics. Causes referable to the nervous system probably occur next in frequency. All young infants may, even in the first year, present evidences of acute cerebral congestion. Extremes of either cold or heat may produce the same result. A child that has been exposed to a strong wind during its daily airing, or one that has had insufficient protection from the sun, may pass a restless and uncomfortable night. This condition must be distinguished from the insomnia of meningitis, which, in some cases, is for many days the only sign. In older children, headache due to overtaxing of the brain is not uncommon. Anæmia and rapid growth, in conjunction with over-study, is a fruitful cause of insomnia. In children of rheumatic parents this tendency is especially marked. Among nervous causes in these older children, hysteria, chorea, and epilepsy are the most common. The young hysterical subject is always liable to insomnia, with or without headache. Some attribute all headaches of this period to hysteria, but the author believes that the distinction should be carefully made between such headaches and those due simply to rapid growth and over-study. The insomnia of epilepsy is peculiar to itself, and is sometimes the only symptom for a considerable period. The child suddenly wakes from profound sleep, sits up, and begins to cry, but soon lies back, as if exhausted, and falls into a deep sleep. These attacks are always accompanied by incontinence of urine. Insomnia complicating chorea is an exceedingly grave symptom. Earache is always accompanied by insomnia, and usually by continuous crying. Hernia is a cause of pain and sleeplessness that is frequently overlooked. Intermittent fever is in some cases marked by wakefulness at a definitely recurring period. Insomnia and headache are prominent and early symptoms of albuminuria.—*New York Medical Journal.*

"Tuberculin" in Tuberculous Diseases of Children.—At a meeting of the Berlin Medical Society, February 7th, Professor Henoch spoke unfavorably of the treatment in pulmonary tuberculosis of children, of whom he had treated twenty by this method. Three of these were in the "advanced" stage, but without fever; they were all made much worse, the fever induced by the injections persisting as hectic. Yet only $\frac{1}{2}$ milligr. (at first he only gave $\frac{1}{10}$ milligr.) was given at the commencement of treatment, and the largest dose was 3 milligr. In one case there was temporary improvement, dulness disappearing, only, however, to return with increase of other signs on continuance of the injections. Another case illustrated Professor Virchow's statements. A girl of eleven years, whose mother had recently died from phthisis, had suffered from a cough for a year; but there were hardly any physical signs, except slight dulness near spine of scapula, prolonged expiration, and some rhonchus at apices. An injection of $\frac{1}{2}$ milligr. gave no reaction. One of one milligr. produced next day a rise of temperature to 38.6° C., and some râles appeared at the left base. Five injections in all were given, and a few days after the last, signs of extensive consolidation of the left lung appeared; and even after a month's interval they had very slightly decreased. Obviously it was not a mere transitory hyperæmia, but whether caseous or catarrhal hepatization could not be determined. There was some suspicion of commencing excavation, for the breathing, which was intensely bronchial, had an occasional amphoric tone, and the râles were metallic. Professor Henoch attributed this change without a doubt to the injections. He said not one of his cases had been "cured," not one "improved," except the one which subsequently relapsed to a worse state; and he was embarrassed to decide if he should continne the treatment in children any longer. It would be ludicrous, in the case of a child, to follow the practice of some physicians, who do not use the injections except at the patient's own wish. Bearing in mind the tendency for tubercle in children to be dispersed in many foci throughout the body, he felt one would be justified in only using it with the greatest reserve, and perhaps at no distant date in discontinuing the practice altogether.

Cocaine in Small-pox.—Drs. Luton and Ory recommend highly the internal use of cocaine in the treatment of variola, having tried it during a severe epidemic that raged in Algiers, in November, 1889. The good effect of the remedy was shown almost immediately by a lightening of the color of the eruption and disappearance of many of the papules without becoming purulent. Even in those cases in which the papules persisted for some time there was no suppuration. One of the cases in which the remedy was tried was one of black small-pox, from which the patient recovered. The cocaine was exhibited in a five per cent. solution, of which from ten to twenty drops were given every six hours. As no pustules were formed, there was no pitting.

ON THE REMOTE EFFECTS OF REMOVAL OF THE UTERINE APPENDAGES.[1]

BY PROFESSOR LAWSON TAIT,

BIRMINGHAM, ENGLAND.

THE fact has now been established in all countries where the art of surgery is practised in a scientific fashion that there are diseases of the uterine appendages of such severity as to demand the removal of those organs in order to relieve the patients from the risk of impending death, to relieve them from intolerable and otherwise incurable suffering, or even for the relief of symptoms which are destructive of health and comfort. It now comes to be a question for calm determination as to how far the application of such an operation can be justified, in the first place, by its primary mortality, and, in the second, by the remote results obtained from it. I have, I believe, completely set at rest the question of the primary mortality by the publication of authenticated lists of cases, in which it is shown that the primary mortality can be reduced to less than three per cent., and therefore all serious objections on that score have ended.

The second question is, however, one not so easily settled, and based upon it we still have from time to time energetic, but, I think, mistaken protests urged against the operation as a whole, while it seems to me that such protests would be more useful and far more effective if they were directed toward the proper limitation of its application.

When the operation was first brought actively under the notice of the profession, and the conditions which appeared to justify its performance were laid down in detail, two sets of opinions were speedily developed in the minds of the profession, both of which, it seemed to me, were mistaken. In the first place, a set of opinions was formed which were entirely hostile to my proposals, and the men who adopted them simply ignored all tha was demonstrated concerning the diseases of the uterine appendages and the effects of the removal of these organs on certain diseases of the uterus. As time passed on, the number of men who entertained those views diminished in number, so that now they are limited, in England, to a few discontented obstetric physicians who cannot operate and who do not care to see their consulting-rooms emptied of a number of well-paying chronic cases who now are speedily and cheaply cured at the hands of the operating surgeon. The last expression of this kind fell from the pen of the obstetric physicians of the Hospitals of St. Bartholomew and University College, a sort of medico papal encyclical letter which beats, for impudent assurance, any truculent outbreak of infallible theologians since the days of the Grand Inquisitor.

The other set of opinions which was developed on the question of the removal of the uterine appendages was much less troublesome but far more dangerous. These opinions occupied the minds of men to whom the performance of operations was a craze, and to whom the mastery of general principles an impossibility. They merely agreed that, given a woman with pelvic suffering, the thing to do was to remove her uterine appendages. The result was the performance of many unnecessary operations, an objectionable result which seems inevitable in the history of all new surgical proceedings.

The operation of removal of the uterine appendages was further and most unfortunately complicated by an altogether erroneous application of the facts of physiology which are known to be applicable to animals being applied, without due inquiry, to men and women, and soon altogether ridiculous conclusions were affirmed, even to the extent of being entirely subversive of conclusions well established concerning animals, and, to some extent, even known to be true about humanity. Thus it is quite well known that in both animals and mankind removal of the uterine appendages (and their analogues in the male sex) some time before the access of puberty will prevent the growth of sexual personalities and the development of the sexual passion, the result being, among other things, that the immature characteristics are more or less maintained—in women the girlish form and character never being entirely replaced by those of the mature woman. It was therefore, and most inconsistently, asserted that women upon whom the operation was performed for surgical reasons, became prematurely old in appearance and acquired certain masculine characteristics as a remote result of the removal of the uterine appendages. Nothing that I have seen in a series of cases, now amounting to many hundreds and extending over a period of nearly twenty years, can be held to do other than completely contradict such ridiculous statements.

It is perfectly clear that the remote results of removing the uterine appendages, in animals as well as in women, before the access of puberty, are widely different from those obtained from the same operation performed after the great physiological change. Further confusion ensued concerning the supposed destruction of the sexual passion, by a total disregard of the dissimilarity of the conditions of animals and those of men. In animals, save when demoralized by domestication, the sexual appetite is governed entirely by the period of rut, and the female animal will not permit of the approach of the male save at the œstrus, and that may be an annual period governed by climate. The human female has no period of œstrus, and permits the access of the male at any time, showing a disinclination only at the menstrual period, which is, therefore, not the period of rut. A destruction of the glands which produce the œstrus would clearly keep the female animal in a constant state of hostility to the male access, but when there is no such arrangement, but really exactly the reverse, the destruction of ovulation (which is really the period of rut in animals), could have no such effect, at least it would not necessarily have it.

In women the access of puberty generally brings with it rhythmic menstruation, and this latter function is now known to depend entirely on the peculiarities of the endometrium, arising from the upright position of the human body. The endometrium alters again to its premolimenal condition about the age of forty-eight, and we then have in women what is known as the "change of life." But in animals there is no such period, and, practically, age never seems to determine the limits of childbearing, as it does in women. Mares, long after age has unfitted them for work, are used for breeding purposes, and I know of a mare that had a foal when she was at least forty years of age. Cats are generally quite tooth-

[1] An address delivered to the French Surgical Congress, at Paris, on April 2, 1891.

less and very aged in appearance at twelve or fourteen years of age, but their œstrus and their powers of reproduction are maintained till sixteen or seventeen years of age, a period of life which would, I think, correspond to eighty or ninety in women. In women, ovulation goes on, as proved by De Sinety and Melassez, and many other observers, till the very end of life, just as it does in mares, cats, and bitches; and but for the specially human changes in the endometrium, there would be no limit to the child-bearing years of women. It is not surprising, therefore, that wrong conclusions have been guessed at concerning the remote effects of removing the uterine appendages in women, when the whole physiology of the text-books has been based upon erroneous assumptions, repeated from one author to another, without due investigation.

When the question is carefully inquired into, and without prejudice, it is found that women have their sexual appetites far less developed than men, a fact explained by the process necessary in evolution, that the male has always been the struggling and aggressive creature. When the child-bearing period of a woman's life passes away, there goes with it a certain amount of her sexual appetite. In a few cases the appetite entirely disappears, but in an equally large number of instances it becomes exaggerated, sometimes grotesquely so. In the majority of women the appetite lessens, and even disappears, during the time of the climacteric disturbance, and then returns to its former condition when the change has been effected. Everyone knows that during the period of disturbances women undergo more or less suffering, chiefly from nervous symptoms. The most characteristic and peculiar symptom is an alternation of rapid changes from heat to cold, the face burns, and seems to be florid and pale in rapid change. The temper of the patient becomes disturbed, in occasional instances even to the length of insanity, and this change is often marked by an especial dislike to her husband. In pronounced cases of this latter symptom I have always found it to be due to a complete loss of the sexual appetite, and an antipathy to sexual congress. Generally, but not always, this change is only temporary, and may last from six months to three years. After the completion of the change the previous conditions are usually resumed, but in a few cases the change becomes permanent.

Had these facts not been wilfully disregarded, or had the critics of the operation now under discussion not been foolishly ignorant of them, much less nonsense would have been uttered on the subject. The indirect and remote results of the operation must necessarily imitate more or less closely those seen at the normal climacteric. This ought to have been, and must be, an *a priori* conclusion, and it is completely justified by clinical observation.

We have, then, two well-established facts to start from, the first, that the known tendency of the operation of removal of the uterine appendages is to maintain rather than to destroy juvenile physical characteristics, and to match in all other respects the process of the climacteric change.

But is is always dangerous to apply the facts of normal physiology, particularly when derived from observations on animals, to the processes of disease, and therefore I desire to place before the Congress the general conclusions, based upon a unique experience, where the operation has been performed for disease.

For purposes of convenience I divide my cases into three groups, even though the division is an arbitrary one. No absolutely accurate division can be made, for many of the cases will be found to overlap from the division in which they are placed into some other. The divisions I propose are, 1, those cases in which the operation is done for disease or symptoms which are uterine, such as myoma, otherwise incurable metrostaxis and incurable dysmenorrhœa; 2, for changes in the uterine appendages, themselves due to inflammatory disease; 3, for conditions and symptoms of a nervous kind, mainly in connection with the menstrual periodicity, and which it is hoped to relieve or cure by the arrest of menstruation. Cases from each division will be found to overlap, as a patient suffering from myoma may, and not infrequently has, chronic inflammation of the uterine appendages, and also may have severe neurotic symptoms; chronic inflammatory disease of the uterine appendages often gives rise to marked rhythmical nervous disturbances, even amounting to insanity.

The evidence yielded by my practice upon the first group is given at length in a pamphlet just published, and from it I extract a few sentences which give my general conclusions concerning the remote results of removal of the uterine appendages for myoma in 271 cases, with a primary mortality of 6 cases, or 2.2 per cent. Of the 265 cases which recovered there were 8 cases in which the results were unsatisfactory, that is to say, where the tumor grew and had to be removed by hysterectomy, or the patients died from conditions which were suspected to be more or less directly associated with the continuance of the disease, as, for instance, the development of myoma-malignant alteration. "This leaves 257 out of a total of 265 cases in which complete cures have been effected—that is to say, in which the symptoms have been satisfactorily relieved—where the tumor has either entirely disappeared, or has so diminished, or has been so satisfactorily arrested as to be no longer a source of anxiety or trouble, and where the main feature of the disease, exaggerated menstruation, has been completely and permanently arrested. . . .

"Concerning the disappearance of tumors after the removal of the appendages and the arrest of menstruation, there can be no doubt whatever that the youth of the patient has a great deal to do with the activity of the process and the extent to which it is carried out. I cannot give the figures which will yield an exact indication of this result, but I think it may be fairly expressed as follows: That under forty years of age about seventy per cent. of the tumors entirely disappear. Between forty and fifty, as a rule, they do not disappear entirely, but become markedly diminished, and after forty-five the diminution is only a shrinking, running between one-third and one-sixth of the bulk of the mass. There have been in my experience, however, remarkable exceptions to this latter conclusion, as I have seen a tumor much larger than an adult head disappear in a woman between forty-nine and fifty after the operation. The ages of many of the patients on the list will indicate very clearly the erroneous belief which exists in the professional mind that the approach of the age at which the menopause usually takes place gives anything like certain relief in cases of myoma, for no fewer than nine of the cases were upward of fifty years at the time of the operation. . . .

"In one case (1,276) the patient has become a complete neurasthenic, but her tumor and the symptoms arising therefrom are completely cured. It may be that her neurasthenia is the result of the operation, but I know of no indication which justifies this conclusion. With one other exception, this is the only case in which nervous symptoms have supervened to any serious extent since the operation. During the process of the climacteric several of my patients became queer for a short time, that is, they were eccentric and ill-tempered, but nothing was more marked in these respects than we often have in women during the normal change of life; in fact, I should say, on the whole, there has been a good deal less of this among these thirty women than if they had been going through the normal climacteric.

"A question has recently been raised by Dr. Thomas Keith concerning the occurrence of insanity after grave operations upon the uterus, particularly hysterectomy, and he has made the statement that it occurs in the proportion of ten per cent. of the cases. This can only be explained as a clerical error or an exceptional result, for it is wholly unsupported by the evidence of anyone else

who has written on the subject. I have operated upon a very much larger number of cases of hysterectomy than Dr. Keith has done, and I know of no case of insanity in my practice. Instances of insanity occur after all surgical proceedings, even the most trivial, and even after the administration of an anæsthetic without any operation at all.

"In the present list of cases one patient alone, so far as I know, has been committed to an asylum, and she is there now (Case 1,453). On reading the report of the case it is quite clear that the woman was perfectly insane before the operation, and Dr. Marriott Cooke, of Worcester, under whose care she is at the present moment, sees no reason whatever to attribute her insanity to the result of the operation. But even if it were to be so attributed, there are three cases in the list in which, for reasons which must be evident I cannot indicate, acknowledged insanity of the most pronounced type has been completely cured by the relief of the sufferings involved by the hemorrhagic myoma; and, in addition to these three cases of pronounced insanity, which have been completely, and, so far as we can see, permanently cured, there are a number of cases of striking eccentricities and ill-temper which have been clearly due to the sufferings, and which have been equally relieved.

"It may be in future, when the method of research which I have initiated in this particular operation is extended to others, that a very much enhanced value may be credited to a large number of our surgical proceedings; but, so far as we have gone, I think it would be very difficult indeed to bring forward instances in which it is at all likely that a higher value could be attained by any operation than in the present instance. The operation not only relieves, but permanently and completely cures, the sufferings of the disease against which it is directed, and I think it must be admitted as one of the most brilliant additions to modern surgery of which we have any knowledge."

Besides the symptoms and conditions induced by the growth of myomatous tumors of the uterus, there are occasional instances in which excessive menstruation, due to unascertainable causes and resisting all such minor measures as intra-uterine medication and the use of the curette and cautery, demands the removal of the uterine appendages as a last resource for the purpose of saving life. In their after-history, as in the purport of the operation, these cases do not differ in any way, so far as I have seen in the small number which have come under my notice, from the cases of myoma.

Cases of extreme arrest of development of the uterus, accompanied by normal growth of the tubes and ovaries, sometimes demand removal of the appendages to relieve the intolerable sufferings involved in the futile efforts of the uterus to fulfil its rhythmic functions. Nor do these cases present any special feature in their after-history and progress. Concerning the second group of cases of the uterine appendages, for changes in the uterine appendages themselves due to chronic inflammatory disease, I cannot speak with the same convincing authority that I can of the cases of myoma, only because I have not had time as yet to trace out a large group of cases and investigate and tabulate their subsequent histories, as I have done in the instance of myoma. Such a proceeding is a work involving a very great deal of trouble and occupying much time. I have, however, a hope that within the next few months I shall be able to report upon some hundreds of cases with results quite as satisfactory as I have established for the operation in the case of myoma.

In the second group the initial conditions are, however, very different from those of myoma, and thereby the operation itself becomes subject to indefinite and indefinable differences of detail. The operation for removal of the appendages in myoma is generally a difficult one—often a very difficult one. In a few cases its completion involves the major proceeding of hysterectomy.

The operation for removal of the appendages altered by chronic inflammatory disease is always difficult. Sometimes the difficulty is so great as to be perfectly unmatched in the whole range of surgery. Many very competent surgeons declare there are many cases where the operation cannot be finished; but that is a conclusion I cannot accept, as increased experience, and consequently greater boldness and perseverance, has enabled me of late years to complete every operation I have begun. I lay it down, therefore, that no operation of this kind should be left unfinished.

This rule, if accepted generally, as it is in my practice now completely established, opens up at once a great road for difference of result, rate of progress, and remote effect of the operation. I never hesitate to overcome the most intimate adhesions of an old suppurating tube or ovary to bladder or intestine merely for the fear of a rent of these viscera. In many cases I have had urinary and fecal fistulæ remain for months after an operation, but I have always succeeded ultimately in closing them. Simple suppurating sinuses, leading deep down into the pelvis, occur in probably five per cent. of all the cases, and they may last indefinitely until they are treated by a special method which I have described as circular drainage. The remote effects of the operation, in a large proportion of these cases, and necessarily in the worst class of them, are on this, and other similar accounts, postponed far longer than are the same results in a case of myoma, where usually there is only the one group of symptoms, generally only one symptom of hemorrhage to contend with. If menstruation is arrested by the operation in a case of myoma, the whole of the trouble is over in probably ninety per cent. of the cases, and the subsequent recovery and convalescence is astonishingly rapid. But the mere arrest of menstruation is not all that is required in cases of old pelvic suppuration, and even less severe cases of chronic inflammation of the pelvis; in fact, arrest of menstruation may not be essential for a cure. Every month there has been not only a great pelvic engorgement inducing profuse menstruation, but there has been a week or ten days of agonizing pain, demoralizing the patient possibly to the extent of inducing her to give way to the excessive use of alcohol and hypnotics. These conditions have thrown the patient out of health in a very complex fashion. The presence of diseased appendages also generally renders marital intercourse a matter of impossibility, or one involving great suffering; and here again a strong moral element of the destruction of health may have entered into the case.

The operation may at once, as in the great bulk of cases, arrest menstruation, but it very often does not arrest at once the pain; and the explanation is precisely that of the pain felt after amputation of a limb in which there has been chronic disease with great pain. The pains remain and recur for months, often for years, after the disease has gone, remain till the nerves which originally carried them have atrophied sufficiently to be useless. In the pelvic operations these pains seldom last twelve months, but during that time they are sometimes a cause of great disappointment to the patient and worry to the surgeon. In four instances where they did not yield, I reopened the abdomen and found that in three instances on one side, and in one instance on both sides, the Fallopian tube, amputated close to the uterus, had formed a cyst afresh. The process clearly was that the tube, being originally occluded quite within the uterus at its proximal end, the cut extremity had closed, thus making an "interstitial" Fallopian cyst. I cut all five of them out, with the result of curing three of the patients at once and completely. The fourth patient unfortunately died of the operation. In order to obtain rapidly the ultimate relief desired in these cases, it is absolutely necessary to remove the Fallopian tubes completely. The remote effects of this operation may, in this group, be completely effected without the arrest of menstruation, indeed, in some of my most satisfactory cases menstrua-

tion has not been arrested at all, but the symptoms demanding the operation have been at once and completely relieved by the removal of the diseased appendages. This constitutes a remarkable difference from the cases in the first group, where, of course, arrest of menstruation is the initial and necessary step for a cure.

When menstruation is not at once arrested, and indeed in some instances where it is, the progress of the case may be most seriously interrupted by the occurrence of an effusion of blood into the structures and between the layers of the broad ligament. There can be no doubt that this is due to the rupture of some blood-vessel whose current resents the obstruction to its flow. Such effusions always occur at the time of resumption, or attempts at resumption, of menstruation. I believe they occur in about four or five per cent. of all operations involving constriction by ligature of the broad ligament. The most serious I ever saw (p. 466 of my work on "Diseases of Women and Abdominal Surgery") was after the removal of a parovarian cyst. I have seen many after the removal of ovarian tumors and after removal of the appendages for all kinds of conditions. They generally give rise to very little pain, but their presence may be guessed at by an otherwise unaccountable rise of the pulse and temperature curves. These effusions were not seen, at least were not noticed, in the old days of the clamp, the heavy mortality of which made finer clinical discriminations impossible, just as it prevented all surgical progress.

In the great bulk of the cases these effusions are of small size and disappear with great rapidity, seldom being discoverable a fortnight after their first appearance, and even if of large size—I mean large enough to be felt over the brim of the pelvis—they give no real trouble if they do not recur and do not suppurate. If they suppurate they require to be opened and drained, and then they materially interfere with the subsequent recovery in the sense that they delay it. Perhaps it may be that the same influence which induces the occurrence of the hematocele prolongs the convalescence of these cases; but whatever the cause, and whatever the effect, it is certain that the cases in which these hematic effusions in the broad ligament occur have the most protracted convalescence, so that instead of the remote results being arrived at in a few months, it is occasionally four or five years before a perfect relief of all the symptoms is secured.

The general conditions arrived at in the remote effects of the removal of the uterine appendages differ essentially in no particular, save one, from those already described as in the first group. This particular is, however, of such importance as to require special indication. In chronic inflammatory disease of the uterine appendages one of the most severe symptoms, and, under certain circumstances, the most distressing, is the inability of the sufferers to endure the agony involved in marital intercourse. In the majority of instances requiring operation this function has to be wholly suspended, or is indulged in only by husbands brutal enough to be insensible to the danger and suffering which it involves for their wives. Removal of the diseased organs permits resumption of intercourse nearly always in a few months; and the temporary disturbance of the sexual appetite by the premature climacteric change effected by the operation, or even its occasional obliteration, is far more than compensated for by its restoration to the sufferers, to whom marital life before the operation was an impossibility. Very much misrepresentation has been made upon this point by a few adverse critics, and even a few weeks ago Dr. Routh, ex-President of the British Gynecological Society, went so far as to appeal to us as Christians not to destroy the sexual appetite in women by removing their uterine appendages. Even if this were shown to be a universal result of the operation, instead of only a very occasional one, I confess it would appear to me to be a strange addition to Christian duty to place upon surgeons, that they should foster, protect, and cultivate the very lowest of the animal passions, that of all others which brings trouble among us. I should look upon a husband who refused to his wife the relief from hemorrhage in a case of myoma, or the relief from danger and constant agony, as in a pyosalpinx, because the operation necessary would make her irresponsive to his sexual attacks, as a mere brute. And I unhesitatingly condemn members of our profession who use such arguments as dirty-minded creatures wholly unworthy of our holy calling. Concerning the third group of cases which I have defined as being such as may justify the removal of the uterine appendages for conditions and symptoms in connection with menstrual rhythm, I have first of all to say that I have avoided the extension of my practice in this direction with a caution which I think has been excessive to the point of mistake. A few cases of decided menstrual epilepsy, that is, cases where the fits have been confined absolutely to the menstrual period, and a few cases of eccentric characters where I have been urged by overwhelming outside influences to undertake the operation, do not justify me in speaking at all positively on this division. In England we have had such a bitter warfare on the previous two groups, where it seems to me that the operation can be defended by arguments and facts that are overwhelmingly convincing, that I have never cared to venture far within the neurotic group. I shall therefore confine myself to the narration, briefly, of two cases over which sufficient time has passed to show conclusively the completeness of the remote effects of the operation in well-defined and extreme cases, and to say generally that I am persuaded that in the group of neurotic ailments the operation has a great future before it—after the present warfare has ended and when its proper application can be studied in peace and without prejudice.

The first case is one of a girl, whose appendages I removed on April 9, 1880, at the request of the late Dr. Green, at that time Superintendent of the Birmingham Borough Asylum, confirmed by the view of Dr. Whitcombe, then Assistant Superintendent and now the Senior Officer. She had been imbecile from birth, and after menstruation developed epilepsy at her periods. This disease increased with her age, until, for many months before the operation, the attacks were simply continuous, that is, for the whole menstrual week she hardly had any appreciable interval free from convulsions, and required the constant care of two strong attendants, who had to be supplied in relays. It was the joint opinion of Drs. Green and Whitcombe that she must speedily die from the mere violence of the convulsions and the impossibility of feeding her if no relief could be given.

After the removal of the appendages she never menstruated, and in a few months the fits diminished till they were represented by a few transient attacks (*petit mal*) at the time she ought to have been unwell. She retained, of course, her original imbecility, but her epilepsy was practically cured.

A lady, aged twenty-five, one of the most beautiful women I have ever seen, was married at the age of twenty-two, and in fifteen months had one child. About a year after the birth of the child it was observed that she presented many unpleasant eccentricities during her menstrual week, at other times being wholly free from them. She was the niece of one of the greatest surgeons then alive, the author of a work on surgery still more quoted than perhaps any other of our text-books. It is needless to say more than this to prove that everything that could be reasonably suggested was done for the patient, but all treatment failed; she went from bad to worse, and was finally, during one of her menstrual attacks, discovered in the act of attempting the life of her only child—a being adored by her at all other times. Her uncle desired that I should be consulted concerning the proposal to treat her by removal of the uterine appendages, and I visited the city in which they lived for the purpose. Finding no physical signs of disease of the appendages I absolutely refused to fall in with the pro-

posal. But in some eight months her condition became so much worse that I agreed to carry out the proposal, placing the entire responsibility of the operation on those who proposed it. Suffice it to say that it completely cured her in a very few months, and that for now more than six years she has not had the slightest appearance of her old troubles, but has led a perfectly healthy and satisfactory life. With such brilliant examples before me I am sure that my passive resistance to the proposal to carry out this proceeding in properly selected cases will give way, and the active hostility even of the old-fashioned English obstetric physicians will vanish. With such brilliant results, even if they be obtained only in a minority of the cases, there can be no doubt the application of the operation will be judiciously extended.

THE QUANTITATIVE ESTIMATION OF SUGAR WITH ROBERTS' FERMENTATION TEST.

By MORRIS MANGES, A.M., M.D.,

ATTENDING PHYSICIAN TO OUT-DOOR DEPARTMENT, MOUNT SINAI HOSPITAL, NEW YORK.

It is not the purpose of this paper to enter into many details concerning the fermentation of grape-sugar by yeast, yet there are inherent in this process two important advantages which deserve notice. The one is that fermentation is the only absolute test for determining the presence of glucose; it is the chemist's crucial test to absolutely distinguish it from allied substances, some of which may have a similar chemical composition, or may reduce Fehling's solution, or may have a right rotary action on polarized light.[1] The other is that none of the usual reducing substances (albumin, uric acid, etc.) can interfere with its action.

The principle upon which all the fermentation tests are based is the well-known splitting up of glucose by yeast into alcohol and carbon dioxide. $C_6H_{12}O_6 = 2C_2H_6O + 2CO_2$. Another reaction occurs which is not expressed in the formula; that is, the specific gravity of the fermenting fluid is lessened in direct proportion to the amount of grape-sugar present. This loss of weight is due not alone to the disappearance of the sugar, but also to the presence of the generated alcohol; it is the presence of the latter which sometimes, though rarely, causes the specific gravity of the fermented liquid to sink below 1.000.

From the above we see that there are several factors which may be utilized in quantitative estimations by this method. 1. The carbon dioxide, usually estimated by volume, as in Einhorn's method. 2. The alcohol; is too complicated and unreliable. 3. The difference in the specific gravity of the unfermented and fermented fluids; may be estimated (*a*) by actual weighing with accurate balance, as is done by chemists; is not adapted for general use; (*b*) by taking specific gravity, as in Roberts' method.

For clinical purposes we are thus reduced to the methods of Einhorn and of Roberts. Einhorn's method being too well known to need description here [2] we shall at once proceed to consider the test proposed by William Roberts of Manchester;[3] and so well has its distinguished author done his work, that, although thirty years have almost elapsed, the method stands practically as originally proposed. The only requisites for the test are a sufficiently wide cylindrical urinometer jar of about two to three ounces capacity, and two good urinometers, one reading from 1.000 to 1.025, the other, 1.025 to 1.050;[4] large subdivisions of the scale are essential. Urinometers with thermometers are desirable, but by no means absolutely necessary. The tests of a good instrument are that in distilled water at the temperature for which it is corrected, the instrument should stand at 1.000, and in a dilution of any salt solution with an equal volume of distilled water the reading should be one half of the gravity of the original salt solution.

The procedure is carried out as follows: Having accurately taken the specific gravity of the specimen of urine, and noted the temperature, about four ounces (if quantity is small, one-half this amount will suffice) are poured into a twelve-ounce bottle, "a lump of compressed yeast about the size of a walnut" (half a cake will be found sufficient) is added and thoroughly stirred up; the bottle is then closed with a nicked cork, to permit the escape of the CO_2 gas generated. A standard is then prepared by filling a two or four ounce bottle with some of the same urine, and is securely corked without having added anything. The two bottles are now put aside in a warm room for eighteen to thirty-six hours, when the fermentation will have been completed, as is shown by the cessation of the formation of bubbles in the fluid, and also by the clearing off or subsidence of the scum. The bottles are removed to a cool place so that they may acquire the same temperature as at the beginning of the test; a portion of the fermented fluid is decanted and the specific gravity and temperature are again noted. It is also well to note the gravity of the "standard," to see if it is identical with the original reading. The difference in the two readings of the specimen before and after fermentation multiplied by 0.23 will give the percentage of sugar in the specimen. Or we may express it thus: each degree of specific gravity lost in fermentation represents one grain of sugar to the ounce of urine. The total amount for twenty-four hours being known, the total amount of sugar can easily be calculated.

Roberts gives two examples. A specimen showed 11.36 per cent. sugar by titration with Fehling's solution, (=49.64 grains to the ounce). The specific gravity was 1.0535; after fermentation it fell to 1.0045; it lost 49°, *i.e.*, 49 grains to the ounce; or, × 0.23 = 11.27 per cent.

A second specimen had 5.68 per cent sugar (=24.82 grains to the ounce) as shown by titrating with Fehling's solution. The original specific gravity was 1.03832; after fermenting it fell to 1.01356; the difference was 24.76°, *i.e.*, 24.76 grains to the ounce; or, × 0.23 = 5.69 per cent.

This method has been very carefully examined by Worm-Müller, the specific gravity having been determined very accurately with the pyknometer. His results[1] as obtained with weighed quantities of glucose were:

	Sp. gr.	After fermenting.	Difference.	Calculated.
				Per cent.
4 per cent. sugar.....	1.03621	1.01819	0.01802	4.1446
2 " " "	1.02851	1.01977	0.00874	2.0102
1 " " "	1.02476	1.02080	0.00426	0.9798
0.5 " " "	1.02290	1.02070	0.00220	0.05060

Based upon the results, he accepts Roberts's coefficients that 1° = 0.23 per cent. sugar, and says, "Roberts's method is an exact method for the quantitative estimation of sugar in urine, which is scarcely excelled by any other, provided the percentage of sugar be not less than 0.4 per cent."

Roberts's coefficient is also accepted by Smoler,[2] Jaksch,[3] Guttmann,[4] and other observers. Slightly different results were obtained by Menassein[5] (1° = 0.219 per cent),

[1] Leo has isolated such a substance, which has the same chemical formula, reduces Fehling's solution, and rotates polarized light to the right, yet differs from glucose in not fermenting.

[2] Archiv Wissens. Heilkunde, 1884, p. 256.

[3] Jaksch: Klinische Diagnostik, second edition, 1889, p. 294.

[4] Deutsche Med. Wochenschrift, 1890, No 1, p. 7.

[5] Salkowski and Leube: Lehre von Harn, 1882, p. 236.

and Antweiler and Breidenbend[1] (1° = 0.213 per cent. – 0.218 per cent.).

Jaksch says, after trying the method on eight cases of diabetes, that "it gives thoroughly reliable results for clinical purposes, and is one which is to be commended, especially to busy physicians, on account of the simplicity and ease of its application." He quotes four cases which were examined with a special apparatus designed to prevent evaporation (which, however, is superfluous), the control-examinations having been made by polarization :

No.	Roberts's method.	Polarization.
	Per cent.	Per cent.
1	2.22	2.25
2	3.55	3.65
3	6.06	6.01
4	6.23	6.00

Guttman[2] highly commends the method after having used it in over one hundred cases. He has simplified the method as follows : In a three to four ounce cylindrical glass vessel the specific gravity is taken ; a quarter of a cake of compressed yeast is added and thoroughly stirred up ; the vessel is covered with a piece of paper and set aside at 15° C. (59° F.) for twenty-four hours. Then the yeast has settled, and the specific gravity is taken in the same vessel at about the same temperature as the original observation. He has ascertained that the temperature changes exert slight differences in the result if the percentage of sugar is over one per cent. ; and if over two per cent. it is reduced to $\frac{1}{2}$ per cent. to $\frac{1}{10}$ per cent. The exact difference is 3° C. (5.4° F.) = 1° ; thus a reading of 1.022 at 12° C. would be 1.021 at 15° C., and 1.020 at 18° C.

He cites three results :

No.		Sp. gr.	After fermenting.	Difference.	Calculated.
					Per cent
1	3 per cent. weighed sugar	1.034	1.0215	12.5	2.90
2	4 " " " "	1.032	1.014	18.	4.14
3	Diabetic urine titrated = 1.63 per cent.	1.011	1.0045	6.5	1.495

I have tried Roberts's method in a fair number of specimens, and the results, from a clinical stand-point, have been very satisfactory. Comparisons were made with Einhorn's method, and the specimens were also titrated with Fehling's solution, as modified by Munk.[3]

I append the results of seventeen specimens.

No.	Spec. gravity.	No. of degrees lost.	Calculated.	Einhorn.	Fehling.
			Per cent.	Per cent.	Per cent.
1	1.037	30	6.90	6.80	7.14
2	1.030	20	4.60	4.50	4.76
3	1.0245	3	.69	.70	.714
4	1.028	10	2.30	2.40	2.60
5	1.0205	2.5	.575	.60	.714
6	1.0245	6	1.38	1.25	1.66
7	1.0215	3	.69	.80	.90
8	1.0315	19	4.27	4.27	4.37
9	1.0315	8.5	1.95	1.75	1.92
10	1.037	20	4.60	4.37	4.55
11	1.028	8	1.84	1.80	2.00
12	1.028	5	1.15	1.10	1.38
13	1.037	27	6.21	6.25	6.41
14	1.032	25	5.75	5.20	5.60
15	1.0255	4.5	1.035	.90	.909
16	1.0225	10.5	2.415	2.70	2.50
17	1.023	8.5	1.955	2.25	2.10

[2] Loc. cit.

[3] Vide paper by W. Mendelson, New York Medical Journal, 1888, vol. 48, p. 5.

[In passing I would call special attention to this modification of Fehling's test, where an immediate analysis is desired, and an estimation can easily be made within twenty minutes. Not alone is the method rendered less time-consuming, but it is made more exact ; as the precipitate caused by the calcium chloride carries down the fine particles of copper oxide so well that filtration may very easily be accomplished, provided we wish to test the end reaction by adding acetic acid and ferrocyanide of potash to the filtrate.]

These figures agree with those of the other observers in proving that there is no constant source of error, but that the result may be more or less than the actual amount. What the cause of this error is I have been unable to ascertain. That it is not due to the urinometer is shown by Worm-Müller's figures, who also obtained higher and lower results although the pyknometer was employed to determine the difference in the specific gravity. Possibly we may find the cause in subtle changes of temperature, or in the secondary fermentation which occurs in the yeast itself. Whatever these influences may be, they are surely not of very great importance, nor do they detract from the claims of this procedure of being called the "Clinical Method," as was proposed by Roberts.

The advantages of the method may be summed up thus : It is simple ; it requires no special apparatus nor special experience ; dilutions are unnecessary, and hence the multiplication of an error is avoided ; impurities in the yeast have very little effect on the result. The disadvantages, besides that inherent in all the fermentation tests, that they are slow, are, that it does not show amounts of sugar below 0.4 per cent., and also that it requires a larger amount of urine. The latter, however, is more apparent than real, for in Einhorn's method we must also have enough urine to estimate the specific gravity.

There are also certain disadvantages present in Einhorn's method from which this method is free. In the first place, gases are much more affected by differences of temperature and atmospheric pressure than are liquids. Then the necessary dilution is a cause of inaccuracy ; Einhorn gives definite rules as to the proportions, as if certain ranges of specific gravity must correspond with approximate amounts of sugar, for he directs that "diabetic urines of a straw color and a specific gravity of 1.018–1.022 may be diluted twice ; of 1.022–1.028, five times ; 1.028–1.038, ten times." There are other ingredients, however, in urine which may markedly affect the specific gravity, *i.e.*, urea, phosphates, chlorides, etc. The analyses already quoted show this very forcibly ; thus, Nos. 8 and 9 of the last table both have specific gravity of 1.0315, yet the one has 4.37 per cent. sugar, and the other, 1.92 per cent. Furthermore, a high specific gravity does not necessarily mean a large amount of sugar, nor a low specific gravity indicate a small percentage. Thus No. 3 of Guttman's cases has specific gravity of 1.011, yet has 1.495 per cent. sugar, and Nos. 11 and 12 of my own series, each with a specific gravity of 1.028, have only two per cent. and 1.38 per cent. sugar respectively. If we do not dilute enough, the gas will pass up into the bulb ; if we dilute too much, the amount of gas will be so small that a large error is unavoidable, because of the subsequent multiplication.

Guttman[1] has also shown that only a small part of the carbon dioxide remains in the long arm of the saccharometer, while the greater part escapes into the air through the bulb. Thus 10 c.c. of a one per cent. saccharine urine ought to give off 24 c.c. of CO_2 at ordinary temperature and atmospheric pressure ; of this only 5 c.c. are registered, while 19 c.c. are lost. (A small amount of the gas may also be absorbed by the fluid.) This objection, however, may be more theoretical than practical, for even Guttman comes to the conclusion that for saccharine urines under one per cent., Einhorn's method gives reliable results.

[1] Deutsche Med. Wochenschrift, 1890, p. 8, where Einhorn's method is critically analyzed.

I would go even further than this, and say that with most urines it gives results which are sufficiently accurate for clinical purposes; but, at the same time, I would assert that Roberts's method is in many respects superior to it. Neither method, however, gives absolutely accurate results. But this applies to every test which has yet been proposed for this purpose, even to the most delicate of them all, polarization and Fehling's test. For the right rotation of polarized light may be partially neutralized by the presence of oxy-butyric acid, which rotates polarized light to the left. As for Fehling's test, we are all familiar with the difficulty of telling exactly when the blue color has disappeared, and we all know how its results may be affected by the reducing action of albumin, uric acid, kreatinin, etc.

OUR MINERAL SPRING RESOURCES.

By J. D. KELLY, A.M., M.D.,

LOWVILLE, N. Y.

The tourist going abroad in the month of June notes with wonder the number of Americans who throng the cabins of ocean-going steamers at that season. Many are evidently in pursuit of entertainment, others rest and relaxation, and some the health-restoring benefits of a season at the noted spas and health-resorts on the other side. If he be at all informed in the mineral water resources of this country, his wonder will seek expression in the query: Why do so many intelligent people cross the Atlantic to avail themselves of what abounds at home? There must be some reason for it. The character of the people flocking abroad implies that. What is it? Fashion, do you say? Yes, in some degree; but converse with them, and you will soon observe that they are going abroad chiefly for the facilities which are assured them at Bad-Nauheim or at Homburg, or at Carlsbad, or at Salins les Bains more than for any implied superior virtues of the waters themselves. With loyal patriotic fervor, they will promptly assent to your complimentary reference to the mineral springs of America and their climatic advantages, in season or all the year round. There seems to be no lack of general knowledge of the quality and excellence of American mineral waters, but there is a decided preference for a season on the other side, for the advantages which are afforded by a full equipment of therapeutical accessories to be found at the mineral springs there.

To know how far this preference is justified by fact, one need only to take a cursory view of the mineral spring health resorts of this country. At most of them the invalid is necessitated to depend solely upon the unaided native resources of the place. Until very recently, the accommodations at the spas of this country were mere hotels or boarding houses where the contest was often between bad culinary resources and the restorative properties of the water. Recently, but in a comparatively few instances, suitable bath-houses, supplied with modern appurtenances, have been constructed, and the virtues of the waters supplemented by a resident staff of physicians. The greater number of our mineral springs, however, are no better qualified than they were fifty years ago. To one conversant with the methods pursued at the spas of Belgium and Germany, the procedures in vogue at our fashionable watering-places appear like travesty. Not alone at our fashionable resorts, but also at the more distinctly remedial resorts, where the waters may be of rare superior merit, the same absence of method and facilities may be noted. The invalid, upon arriving at one of these mineral springs, is told that the water of this spring is cathartic, of that one diuretic, and, in the absence of a medical director, he assumes that the one or the other will fill the requirements of his case, and he proceeds to avail himself of the opportunity. He drinks the water, and, if any means be at hand, he bathes in it. His only method of procedure is suggested by his own taste or the directions given to him by someone there who has received benefit. It is assumed that what has helped conditions in one case, will also help in another where there is any approximation of symptoms, real or imaginary. Full of hope and expectation and faith to make him whole, he proceeds by drinking too much, or too often, at the wrong time, in the wrong manner, or at all times. The weak stomach is flooded, and dilatation, hyperalkalinity, or acidity aggravated. Failure of his appetite or digestion attracts his attention, but filled with confidence by the improved cases, he attributes it to any but the right cause, and perseveres till the conviction is forced upon him that he is certainly getting worse. The inconsistency of seeking at the hands of a physician at home a prescription for ten grains of potassium bromide on the one hand, and of drinking *aa libitum* the sulphates, chlorides, and bicarbonates in solution in mineral spring water on the other, does not appear to occur to him. In this way kidneys at the point of acute nephritis may be hurried on to speedy destruction; the liver in some degree of atrophy or hypertrophy, may be soon rendered wholly incompetent; and affections of the glandular system, and of the mucous tract generally, take their chances in this haphazard treatment. Disappointed at length, he may leave one resort to go through the same inappropriate course at another, or, wholly discouraged, he may abandon all pursuit of health in this direction, and return to his pills and cataplasms at home.

What wonder is it that confidence in the value of a season at our watering-places is often very small! As one, with due appreciation of the requirements of such places, considers how deficient they are in supplemental facilities, it is rather a wonder that they have sustained even the reputation attached to them; and that reputation, greater or less, persisting through all such adverse conditions, indicates the great value inherent in our mineral waters, and is suggestive of their superior possibilities under adjuvating circumstances.

The neglect of requisite accessories in the matter of baths and of bathing is even more conspicuous, and any comparison with European spas in this feature consequently more disparaging to us. Balneotherapia has not yet become a deservedly prominent feature of therapeutical procedures in this country. At our mineral springs resorts, where all the indications for its exercise are the strongest, one sees little of it, and that little as often incompetently exercised. In the absence of medical supervision, invalids exercising their own tastes or notions in the matter, not only fail often to appreciate the curative properties of the waters, but in many cases they aggravate, as in drinking the water, existing derangements, and even engender unexpected complications. The value, the potency of a therapeutic measure, may often be estimated by the deleterious effects of its maladministration, and one needs only to study the consequences of undirected bathing in mineral water, in some instances, to obtain a due appreciation of the potency of that agency in therapeutics. With this in mind, I have often looked upon the inadequate appurtenances at most of our mineral springs as a safeguard of the character of prevention or limitation, for, were the mechanical facilities complete, there can be no question that invalids conducting their own cases in absence of competent medical direction, would, as in drinking the water, oftener suffer the consequences of derangement engendered in this way than derive the benefit which naturally follows the proper use of the baths. The weight of this consideration is appreciated when we observe the prompt and decided effect of the cold, tepid, or hot bath, in even plain water, upon the skin, the circulation, and the reflexes upon the nerve-centres and organic function. No agent in medicine produces more prompt local or general effect. Every experienced and observing practitioner knows how, in emergency, in crises, the potent influences of the bath are enlisted, supplanting all medicine temporarily set aside.

Commensurate with such potency for good is its power to damage. As well place any or all the more effective drugs or keenest instruments in the hands of invalids for self-use and self-treatment, as to advise the unrestricted and undirected use of the baths at mineral springs. The principle is the same, and the consequences quite as deplorable. And yet this is just what is done. The invalid, voluntarily or acting under some suggestion, visits one of our mineral springs, and, in the absence of competent professional direction, proceeds, quite as invalids do, in drinking the water. He bathes too often, too long, at the wrong time, or in the wrong manner. Whereas his condition would be benefited by warm baths, he takes them cold, or *vice versa*. While his case may require local treatment, as with the douche, he may depend upon simple general immersion. Lesions readily amenable to suitable administration of the baths, or to electro-balneotherapia, are considered intractable under the unaided course he pursues, and the discredit attaches at once to the waters as inefficacious.

It is very refreshing, however, to observe the improvements and advances recently made in proper equipment of some of our mineral springs. As an instance worthy of emulation, I may mention the new bath-house and its appurtenances at Richfield Springs, N. Y. In adaptability of architectural design, in arrangement and variety of its baths, and in scientific facilities for the therapeutic employment of the waters, I commend it to the proprietors of mineral springs as a model up to date. Withal, a competent resident physician is in charge, with an office in the bath-house, in complete supervision of all therapeutic measures which the place affords. The waters at Richfield, however, are of the sulphur class, and are applicable chiefly to affections amenable to sulphur in therapeutics. On the other hand, at Massena Springs, N. Y., where the waters, of the saline class, are of rare and excellent properties, the only means of employing them in the bath are very simple, and the only therapeutic effect therefrom is limited to what may be obtained from leaving the body in them. The valuable therapeutic properties of these waters are comparatively unavailable, locked up under the primitive conditions which some near day, it is to be hoped, will be displaced by the hand of science and the waters applied as their properties merit. Again, at Chester Springs, Pa., we have an instance of *relapsus*. The waters there, some of the sulphur and others of the saline and chalybeate classes, are of excellent properties, and at one time were frequented by invalids in goodly numbers. The only facilities, however, were bath-houses of very simple design constructed over the springs, with one common well or swimming pool in the centre, surrounded by a narrow platform upon which the dozen or so dressing-rooms opened. With no professional supervision and with facilities so rude and limited, it occasions no wonder in one competent to estimate these things, to see this resort now entirely deserted, its bath-houses in tumble down ruins, and this beautiful place, so endowed by nature, given over to grazing and watering cattle. I believe the time is at hand when these favored places will be rehabilitated, and, equipped with the appurtenances of recent balneo therapeutics, become what the great Physician evidently designed them to be: for the healing of the nations.

Recent researches and discoveries in bacteriology have created new interest in the constituent properties of mineral waters and in the rationale of their therapeutic action, particularly those of the sulphur class, and those of the saline class containing the chlorides. Notably, waters containing the chloride of calcium in appreciable quantity are attracting, in the new light of recent discoveries, increasing interest in the discussion of infiltrated glands, the treatment of tubercle, of cutaneous affections, rheumatism, etc. The value of the chloride of calcium as a therapeutic agent has long been known in medicine, but in connection with bacteriological study is recently attracting new interest. It received special commendation by so eminent authority as Professor Wm. H. Thomson, at a recent session of the New York Academy of Medicine, with particular reference to its rare and superior virtues in the treatment of scrofulous conditions. The value which this salt imparts to mineral spring water is very high, not alone for its efficient properties, but because it is comparatively rare even as an appreciable element in mineral spring water. In the water of one of the springs at St. Clair, Mich., 2437.491 grains are present in each gallon, and therefore give to that water a rare and distinctive potency in the treatment of affections of the scrofulous and rheumatic diathesis. When waters containing efficient elements like this are supplemented by electrical apparatus to obtain cataphoretic effect, their efficacy is greatly augmented and the therapeutical results sometimes really wonderful. The bath-house and its appurtenances at St. Clair Springs is another very pleasing and promising instance of adequate modern equipment. A resident medical superintendent and competent staff direct the administration of the waters, and adapt them properly to each individual case. The growing popularity of these properly equipped health-resorts is attracting attention, and will contribute in no small degree to the movement yearly growing greater for putting our unsurpassed mineral springs in competency to lend their virtues to the healing our sick, and, in doing this, spare them the fatigue of travel abroad.

The bounty of mineral springs in all parts of the world, implies a design as beneficent and direct as do the natural deposits of gold, silver, iron, coal, and oil. The great Chemist in adapting their several constituents was not without a purpose, the wisdom and providence of which are more and more discerned and appreciated as the world develops toward competency. As we progress in time we shall see the resources of mineral springs more and more developed and utilized in therapy, and in this country particularly, more and more adequately equipped for all procedures in balneotherapia. The growing interest of many of the best and brightest intellects of the profession is demonstrated by the number and character of new works on balneology, each year increasing in number and value. The field for study and investigation opened up under the light of recent advances in bacteriology and in scientific appurtenances is very inviting, particularly to the student in balneology, in so far as the rationale of the therapeutic action of mineral waters is thereby unequivocally indicated.

Treatment of invalids at mineral springs implies more than the mere application of the curative properties of the waters. It implies removal from the confines of the sick-room, the shop, or the counting-house, to the superior hygienic conditions of a well-arranged health-resort. It implies change of air, of scenery, of surroundings, and of companionship, any or all of which may be the most essential to recovery. In those months of the year when attendance at mineral spring health-resorts is the greatest, the native beauty of such places, together with the charms of the season, render the change of the greatest value and of the greatest interest to the ailing. The usual proximity of such resorts to some body of water as the sea, a lake, or river, happily supplies a valuable adjunct in the way of varied and entertaining outdoor exercise, as rowing, fishing, etc., while the adjacent fields and forests afford entertainment for the artist, botanist, trapper, and hunter. In addition to all such the accessories of the modern bath-house include a gymnasium, ball-room, bowling alley, billiard-tables, tennis court, and other games and exercises which serve to supply grateful exercise of the body, and to divert the mind from gloomy introspection and entertain it in its engaging surroundings. By proper direction these all may corroborate the efficacy of the waters in a most agreeable manner, and adjuvate their curative action to an otherwise unattainable degree. By such means invalids deemed helpless or hopeless at home readily improve, and year after year return to the springs in health for a season of entertainment under the condi-

tions that restored them when ailing, more as a system of engaging amusement than as a process in therapeutics.

The adequate development of our mineral springs will prove a great auxiliary to the purpose of our profession. It will afford us suitable conditions for invalids convalescing from acute disease, at a time when proper care of such cases is of greatest importance, and when domestic conduct so often frustrates the object and result of preceding professional management. It will provide us with conditions adapted to the proper conduct of cases which are not to be benefited by drugs, and furthermore, for such as have developed an utter abhorrence for medicine in any pharmaceutical form. The invalid who recovers health under ordinary procedures of medicine, looks upon his physician as something more than the medium through which that greatest of blessings has been restored to him. The invalid who regains health by means of the waters of some mineral spring, feels a sentiment of gratitude welling up in his heart as the waters bubble up from the earth, free, pure, spontaneous, reflecting the bounty and wisdom of the great Dispenser.

SHOCK.

By F. E. BUNTS, M.D.,

PROFESSOR OF PRINCIPLES OF SURGERY, MEDICAL DEPARTMENT WOOSTER UNIVERSITY, CLEVELAND, O.

REGARDED as an abstract term, the word shock conveys to the mind an impression varying largely with the experience and personal observations of the individual. One has seen the sudden collapse and even death resulting from a blow upon the epigastrium, and recognizes it as shock. Another looks upon the victim of a railway accident and sees the crushed muscles and nerves and comminuted bones and is not surprised to find that here, too, is shock; and though the complete and sometimes fatal collapse which may follow unwelcome news, or even joyous tidings, may impress the same observer as something to be accounted for on psychical rather than physical grounds, yet he is forced to recognize it as one of the undoubted forms of shock.

Here, then, we have an occult agent whose baneful effects are shown in the most varied range of cases, and yet presenting such a characteristic group of symptoms that we are forced to believe it identical in each, and it is to this grouping of symptoms, all indicative of a profound impression upon the nervous, or vascular system, or both, that the name of shock has been given.

While some difference of opinion exists as to what portion of the nervous system is primarily affected, yet most are agreed, I believe, that shock is the result of a sudden and violent impression upon some part of the nervous system,[1] acting not alone, as some few would have us believe, upon the heart, but upon the entire blood-vascular system. And while it is not to be denied that many or all the organs of the body may sympathize in the prostration which ensues, and make this sympathy known by various symptoms depending upon their location and function, yet these disturbances are readily accounted for in view of the manifest disturbance of the nervous and circulatory systems, and must, therefore, be regarded as entirely secondary. The importance of bearing this in mind is made manifest when we come to consider the treatment.

It is to be regretted that the pathology of shock is still a debated question, though it is doubtful whether its elucidation would add anything to the means already used for combating it. Travers regarded shock as the result of nervous influence upon the heart alone, while Mansel-Moullin suggests that since the heart is but a higher development of the blood-vessels themselves, and since they are all co-ordinate parts of one system, they are all, probably simultaneously influenced in the same direction by a single stimulus, and Goltz's experiments on a frog lead us to believe that shock results from reflex paralysis of vascular nerves, especially of the splanchnics (according to Fischer), following traumatic concussion. The stasis in the abdominal veins and the afflux of a large proportion of the entire mass of blood into the dilated vessels of the intestinal tract, in consequence of the reflex paralysis of the intestinal vaso-motor nerves, cause anæmia of the brain, skin, and muscles, and thus leads to all the grave symptoms of shock.[2]

Naturally, but little can be learned of the workings of this obscure condition by post mortem examinations. Rigor mortis is usually present in cases of death from shock, no alteration can be discovered in the nervous system itself, and the condition of the heart varies with the mode of death. Where this has followed instantaneously upon the receipt of the injury or nervous impression the heart is found empty or nearly so, but when it has been delayed we shall ordinarily find the heart dilated and gorged with blood.

The causation of shock may, perhaps, be divided into exciting and predisposing causes, and under the latter head we are obliged to recognize certain idiosyncrasies of the person. Thus, every surgeon has had occasion to notice the excessive shock which so often occurs after apparently minor injuries in those who have led a life of debauchery and excess. It is well known, too, that age is an important factor. Thus in youth the shock is rapid and extreme, yet under favorable circumstances the reaction is equally rapid and pronounced. In old age, however, the shock is apt to be less pronounced, while the reaction, owing to the previously enfeebled and unfavorable condition of the patient, will often be slow, and many times, while apparently making a gallant fight for recovery, the weakened and over-strained heart will suddenly cease its action and the patient is gone, even while we are congratulating ourselves that he is rallying nicely.

Unusual dread of an operation, or a settled conviction that its outcome will be fatal, increases the likelihood of shock, as does also disease of important viscera, such as the liver or kidney, while exposure to cold, loss of blood, and various other debilitating agents not only predispose to it, but increase it when present.

The study of the exciting causes of shock is most interesting, extending, as it does, over the widest range of physical and mental impressions. Sudden and severe injuries causing contused and lacerated wounds are among the most frequent causes of shock, and, naturally, these are most often found in machinery, railway, and gunshot wounds.

Speaking in a general way, the nearer the wound is to the great centres of intellect, circulation, and digestion, the greater will be the shock sustained,[3] though the slightest injury—as the prick of a pin—may cause profound shock and death; and minor operations, such as the avulsion of a toe-nail, may cause alarming symptoms of shock.

The profound collapse following a sudden blow over the epigastrium is familiar to all, "but it is not a little singular that, in spite of the generally received traditions on such matters, and of the undeniably grave symptoms which are so notoriously produced, there should not be recorded one single case in which death has followed in a healthy man immediately upon a blow on the abdomen without injury to any of the subjacent viscera."[3] Sir A. Cooper relates a case of a man being struck in the abdomen by the handle of a wheelbarrow which he was pushing, and dying instantly, but no autopsy was held to prove that it might not have been due to some organic lesion of the heart, or possibly an actual injury of some of the subjacent viscera.

Falls upon the head or back or sudden blows inflicted in this region are peculiarly liable to produce symptoms of shock, though even here they must be carefully differ

[1] Savory.

[1] Rosenthal. [2] P. S. Connor. [3] Mansell-Moullin.

entiated from those which follow upon actual injuries of the brain and cord.

Injuries of, or operations upon, large joints are said to be frequent causes of shock. This I have uniformly observed to be the case in amputations at the hip-joint, but I have repeatedly performed, and seen performed, excisions of the knee and hip-joint without the slightest symptoms of shock.

Injuries of the testicle are often followed by severe shock, as is also division of the cord in its removal.

The passage of a renal or biliary calculus or the sudden onset of acute peritonitis may develop a severe, though not usually fatal, condition of shock. Agnew gives as one of the exciting causes the serous discharges of cholera. While the utter prostration brought about by these discharges bears a close relationship to that of shock, yet its origin and our conception of the pathology of shock would seem to exclude it from this category.

Even simple fractures and dislocations are often accompanied by shock, while it is an extremely frequent occurrence when the fracture or dislocation is compound instead of simple.

The marked depression following the sawing of a bone in amputations has been noticed by nearly everyone, and this is the more to be wondered at, since we have been led to suppose that the nerve distribution to bone is very small. It is, therefore, difficult to account for this shock upon a theory which requires for its development a marked and sudden impression upon the nervous system, unless it be that the peculiar laceration produced in the act of sawing acts as a causative agent.

Burns, especially those involving large surfaces, scalds, perforations of the bowels, extraction of a tooth, electricity, the removal of large tumors, may all produce shock, and that, too, of such a severity as to be followed by death.

The relief following a long and severe pain, as in a protracted labor, has produced fatal shock.

The evil effects of profound mental impressions are well known, the long-continued strain caused by delayed operations places the patient in a somewhat unfavorable condition, and deaths from shock following minor operations have been traced to this cause. Great fright is a frequent cause, and Desault relates a case in which a patient fainted and died while the surgeon was simply tracing with his finger-nail the line of incision upon the perineum, the patient being under the impression that the knife was being used. Similar cases are of comparatively frequent record.

As mentioned in another part of this article, welcome though unexpected news, as well as disagreeable news, as of the loss of dear friends or relatives or of property, may cause profound shock, and Savory gives a case in which permanent deafness has followed shock caused by sudden fright.

The symptoms, varying chiefly in degree, are somewhat constant, but "the most important of all is the reduction of temperature."[1]

Taking a marked case for example, the utter prostration of the patient impresses one at a glance, the lustreless eye, pale lips, shrunken features, drooping eyelids, cyanotic skin bathed in a cold beady perspiration, dilated nostrils, short and feeble respiration, all point at once to the nature of the case. The pulse is frequent and irregular, sometimes it is entirely absent, vomiting is frequently though not invariably present and cannot be regarded as particularly unfavorable. There is great muscular debility and relaxation. The urine is often retained, while the relaxation of the anal sphincters gives frequent rise to involuntary evacuation of the rectum.

The mental condition is of peculiar interest, differing, as it does, so essentially from that present in syncope. While it may be confused or bewildered, yet the patient can usually be roused by a sharp question, and will answer in a perfectly rational manner. Ordinarily there seems to be an inability to think or reason, yet at other times the intellect is almost preternaturally clear, and the patient continues talking to his friends and attendants up to the very moment of his death, saying good-by, arranging his worldly affairs even to their minutest details with an astonishing degree of judgment, consideration, and perception. Vision is dulled, the pupil is dilated and reacts slowly to light, and the entire cutaneous sensibility is greatly diminished though not usually abolished. The respiration is shallow and irregular, occasionally abnormally deep and of a sighing character, or accompanied by a constant moaning, and the patient is either absolutely prostrated and unable to move or he is continually tossing from one side to the other, begging for water, which he no sooner swallows than it is vomited, pleading for a change in position, and impressing the observer with the feeling that he is tired beyond description. The blessing of sleep is denied him, and if reaction does not occur the symptoms grow progressively worse, the restlessness and jactitation continue without interruption, a wild and frightful delirium comes on, in which, as in one case I have seen, the patient made repeated and determined efforts to choke himself to death, or, as is more frequently the case, imagines that he is surrounded by those who seek to do him bodily harm; and later these symptoms subside, the pulse cannot be distinguished, the eyes become fixed and filmy, and an occasional long-drawn gasping respiration is the only indication that death has not yet closed the scene.

The prognosis in cases of shock is, of course, variable, and depends so largely upon the individual case that it is difficult to make any but general deductions concerning it. The more pronounced the shock and the longer delayed the reaction, the more unfavorable must our prognosis be, and yet it is well known that the slightest injury may produce instant and fatal collapse. The loss of blood, however small in amount, is unfavorable, as is also old age or a previously enfeebled condition. Reaction may follow almost instantly upon the receipt of shock, or may be delayed for several hours or days and then terminate favorably.

The proximity of the wound to the centres of intellection, circulation, and digestion has a marked influence upon the prognosis, the danger being the graver the nearer the injury is to one of these centres, and when the intraperitoneal viscera are damaged the shock is greatest, due no doubt to their intimate connection with the semilunar ganglion.[1] The loss of power of swallowing, or the insensibility of the conjunctiva when touched, indicate a profound depression of some of the higher centres, and are, therefore, to be regarded as of grave import.

There is a condition supervening upon incomplete reaction which Travers has called prostration with excitement, and which is described by Savory as "marked at first by a dry heat of the skin, a flushed face and anxious expression, a rapid and bounding pulse, which is sometimes even sharp, but always easily compressed. The respiration is hurried and imperfect, with partial and irregular sighs. The tongue is tremulous; there is often urgent thirst, vomiting is a frequent and sometimes most obstinate symptom; there are occasional rigors. The languor or stupor of collapse is succeeded by restlessness, jactitation, tremor and twitching of the muscles, præcordial anxiety, often, but not always, delirium of various degrees, from occasional incoherence to wild and fierce excitement; this most frequently occurs, and is more marked, during the night. There is an entire absence of sleep, or it is partial and interrupted, and is succeeded by no relief; as the exhaustion increases the skin becomes covered with a cold and clammy sweat which is very often profuse. The face becomes pale and the expression haggard; the pulse innumerably rapid, irregular and fluttering, subsultus comes on; slight convulsions, coma, more or less profound, and death."

This condition of prostration with excitement is referred to by every author whom I have consulted, yet no-

[1] P. S. Connor.

[1] P. S. Connor.

where do I find any explanation for it except that it is due to incomplete reaction from shock. I have, therefore, made this liberal quotation from Savory's most excellent article, because the description is graphically true to nature and represents a condition which every physician and surgeon has met.

It seems obvious to me that a dry heat of surface, a flushed face, and bounding pulse are inconsistent with our conception of shock, whose most marked symptoms are a reduction of temperature, a cyanotic surface, and an almost if not quite imperceptible pulse. I doubt if Mr. Savory himself could give a more vivid and truthful description of septicæmia than that which he has portrayed here under the antiquated title of prostration with excitement.

I desire the more particularly to call attention to this subject, since nowhere have I found the slightest allusion to what I conceive to be its true nature. The very condition of shock, it seems to me, where dependent upon an injury, must predispose to septicæmia; the feeble circulation, the non-absorption of clots and broken-down tissue, or the open wound, neglected perhaps in the endeavors to bring about reaction, form a midus of infection only too apparent, and it is not astonishing, therefore, to see a case in which reaction is beginning progressively develop those symptoms which I believe to be septic in character and which have so long passed under the name of prostration with excitement. If this be incomplete reaction, it is because a new affliction has befallen the patient; he has recovered from shock but is suffering from an equally or even more dangerous malady, septicæmia.

We cannot be too careful in our acceptance of so called cases of delayed shock. It is usually in railway accidents that such a condition is developed. The description usually given is that a man is in a railway collision, suffers a great jar but escapes apparently uninjured. He even goes about assisting others and feels perfectly well until the following night, when he finds himself unable to sleep, grows restless, nervous, complains of various pains, and paralysis or coma and death may result.

In these cases there is, probably, a direct injury, such as the rupture of a blood vessel in the spine or brain, and the symptoms are due to a gradual extravasation of blood, as in the case of a man who fell from a height, striking on his head, in a few moments he was seen by a doctor, who examined him and failed to find any injury of a severe character, the man was perfectly conscious and able to stand up. He was sent home, a considerable distance, walking all the way, but upon his arrival at his house he was overtaken with alarming symptoms of collapse. The family physician and a consultant were called, the former insisted that it was simply shock and that the patient would recover, the consultant, however, diagnosed a cerebral hemorrhage. The autopsy revealed a large blood-clot in the brain. Could an autopsy be held in every case of delayed shock, I am satisfied that the cases reported would be much fewer than at present; for, as in the so-called concussions of the brain and cord, we would, I believe, in the vast majority of cases find an actual and perceptible lesion.

It is necessary to remember in rendering our prognosis, particularly in those cases consequent upon fright or other mental emotion, that a nervous condition is liable to ensue which may cling to the patient for years or perhaps till his death. Thus, in a case which I have seen, a woman was so frightened by being wakened from a sleep by a volcanic eruption that she has been troubled with almost persistent insomnia ever since, being unable to throw off a feeling of impending danger the moment she touches her bed.

Permanent deafness has followed shock from severe fright, and death may, of course, be the final result in this class of shock as well as in the case of actual bodily injuries. A marked fall in temperature is of unfavorable import, and when it reaches as low as 96° F. the result is, probably, necessarily fatal.

Among the favorable prognostic symptoms are increased strength of pulse with diminished frequency, greater regularity of respiration, disappearance of cyanosis, return of bodily warmth, voluntary motion, lessened irritability of the stomach, and it sometimes happens that the clearing of an overloaded stomach by vomiting will be followed by marked improvement in pulse and respiration. It must not be forgotten, however, that even after reaction appears to be established, relapses may occur, or an exhausted or over stimulated heart give way and death ensue.

In the treatment of shock we must keep constantly before us the condition of the pulse, respiration, and temperature, and our efforts be directed toward their improvement. Warmth, in the form of a hot bath,[1] or of hot plates, bottles, irons, etc., applied to the chest, abdomen, and extremities, is of prime importance. Even when life seems to be extinct, as in the case of a boy whom I had trephined for a crushed skull, reaction may sometimes be brought about by wrapping the patient from head to foot in a flannel blanket wrung out of water as hot as the hands can tolerate.

Stimulants are indicated from the start, and should be persisted in until reaction has begun, when they must be diminished, or administered in conjunction with nourishment either by the stomach, or when this will not retain it, by the rectum. I believe that the danger of over-stimulation is genuine, not on account of any fever which may ensue, but rather lest the enfeebled heart may succumb to the excessive demand made upon it. Of all the stimulants recommended the greatest hope is to be placed in brandy or whiskey, then digitalis, and then strychnine, all to be given hypodermically or by the rectum. Brandy and whiskey can be given in syringeful doses repeated very frequently, digitalis in ten-minim doses of the tincture or one sixtieth grain of the alkaloid, and strychnine in one-thirtieth or one-fifteenth grain doses, though not repeated so often.

Verneuil recommends injections of ether, at times an excellent stimulant. Carbonate of ammonia is valuable and may be given subcutaneously. Morphia and atropia are of great value when restlessness or delirium is present and should never be withheld in such cases.

Artificial respiration will often prolong and sometimes restore life and should be resorted to in suitable cases. Bleeding from the external jugular has been recommended,[2] where that vessel is found distended with blood, with the hope of relieving the engorgement of the heart and thus stimulating it to action, but it must be remembered that the paralysis of the heart is not due to its engorgement, but that this condition is rather dependent upon the paralysis, making the operation one of doubtful expediency.

Transfusion may, possibly, be of service when there has been loss of blood, in which case a weak saline solution will be quite as efficient as blood itself.

But little can be done to relieve the excessive irritability of the stomach, except to withhold absolutely everything from it. The patient's lips may be moistened, but nothing must be swallowed, and the extreme thirst may be slightly relieved by rectal injections of milk or water. A mustard plaster applied over the stomach sometimes seems to give relief.

There is one more important question to be considered before leaving the subject of shock, and that is the time at which operations should be undertaken when the patient is already in shock.

The general rule has been to operate when reaction has taken place; but I am satisfied that many lives have been sacrificed by this unmasterly inactivity of the surgeon.

Guthrie advises waiting till the pulse is beginning to regain some of its strength or till the patient is recovering his sense of pain. This is good advice if the waiting be not too long, but when the shock is profound and re-

[1] Hunter. [2] Savory.

action shows no sign of coming on after the lapse of one or two hours the operation had better be proceeded with; indeed, personally, I am in favor of administering stimulants actively for a short time, not to exceed half an hour, applying artificial heat to every available point and proceeding with the operation, the patient being placed completely under the influence of an anæsthetic, believing that the continued presence of a crushed and mangled limb tends to perpetuate the shock and renders septicæmia more probable than a prompt and rapid bloodless removal of the part.

ABORTING PNEUMONIA.

By OLIVER J. ROSKOTEN, M.D.,

PEORIA, ILL.

In view of the dreadful mortality from pneumonia at the p esent time, any suggestion bearing on treatment must be of interest to the medical practitioner. Limited though my experience be, I give it for the benefit of others in the hope that a trial by unbiased men may confirm the observations which I have made in a few cases.

In company with others I find that in acute lobar pneumonia (to which variety alone I now refer), after exudation and consolidation have taken place, I am nearly, if not quite, powerless to modify the course of the disease under any treatment now in vogue. This deplorable fact was very forcibly impressed on me some time ago by the loss from heart-failure of several patients in quick succession. After prolonged consideration I concluded that the period most promising of success in medication must be that preceding the exudation, *i.e.*, the stage of engorgement, that in which, beyond excessive vascularity and perhaps some moderate effusion, no great anatomical change has yet disturbed the recuperative powers of the lung threatened.

Can pneumonia be diagnosticated thus early?

I find that with reasonable certainty it can, at least if a severe chill and other symptoms to be named are accepted as sufficient. The chill comes on suddenly in a person previously of good health, is rapidly succeeded by stitch-pains in the side (or at some one of the less frequent points, *e.g.*, the lateral part of the epigastric region), by short, suppressed, locally painful, dry cough, somewhat accelerated, superficial respiration, elevated temperature and pulse-rate, with just noticeable dulness on percussion, respiratory murmur only tinged, as it were, with a tubular element, and a larger or smaller number of the ominous fine, crackling, crepitant râles audible on deep inspiration over the affected, but as yet limited, area at the base. The respiratory murmur here has lost its soft rustling character, is probably weakened by instinctive favoring of the opposite sound side, and there is exaggerated.

No one can deny the close relationship between the skin and the respiratory organs. Sudden suppression of cutaneous exhalation ordinarily is quickly followed by a catarrhal state of some portion of the air-passages, but the noxious influence developed through disturbance of the function of the skin may skip the less important and generally less resisting mucous membranes, and precipitate an inflammation in the deeper parts. Why this should occur we can only surmise. I take it as probable that the respiratory centre does not alone regulate the proper working of the main respiratory mechanism, but that of the subsidiary organs, especially the skin, as well. Its connections with the vaso-motor centres and nerves must hence be very complex, and one can understand how it must be exposed to frequent disturbances, I may say strains, on its integrity by abnormal influences reaching it from all the organs over which it presides.

I, therefore, regard acute nasal, laryngeal, bronchial catarrhs, and even acute croupous pneumonia, as so many manifestations of disturbed equilibrium between the respiratory and the vaso-motor centres, the localization of the affection depending on the intensity and other characters of the primary irritation, as well as upon the condition of the centre itself.

I determined to make some impression on this centre, be it good or bad, in the next case of pneumonia which should chance to fall into my hands, intending thus to gain an experience which would guide me to a rational therapeusis in other cases. I decided upon jaborandi, and soon had an opportunity to test it.

A fairly strong cattle-feeder in one of our distilleries suffered a prolonged wetting of the feet at his occupation, and was well soaked in a rain storm on his way home. He was that evening seized with a violent chill and all the symptoms enumerated above. A few hours later I made the diagnosis of acute lobar pneumonia, located at the right base. I placed him on the following inelegant mixture:

℞.	Extr. fl jaborandi	iij.
	Liq ammon. acet	j.
	Tinct. aromat	ij.
	Syrupi aromat	j.
	Aquæ dest q. s. ut ft.	iv.

M. Sig.: Tablespoonful every hour until thorough effect, then half doses every two hours.

I also ordered a hot pediluvium, and some mild counter-irritant. After two doses a most profuse diaphoresis ensued, which was prolonged by lessened doses of the medicine until I saw him next morning. The temperature, previously 103° F., was now found to be 98° F.; pulse, 80; some stitch-pains left, but general condition vastly improved. The local signs had not progressed. Little or no salivation. As there was no occasion for any change in medicine, the patient was directed to continue the remedy at longer intervals. My astonishment can be imagined when at the third visit, next day, I found the bird flown, himself and family to this day doubting my diagnostic acumen!

I have practised this method in four cases since then, with three signal successes, while the fourth, a failure, was probably an instance of mistaken diagnosis; anyway pleurisy was recognized a few days later, though pneumonia may have existed and been aborted.

I have confined this treatment to the earliest stage of the variety known as acute lobar pneumonia, and cannot speak of experience in any other, but during last year's run of la grippe I have freely used the remedy, with the result that I have not met with a single instance of pneumonia in the course of the epidemic, although the number of cases treated was quite large.

The theoretical objection to jaborandi or pilocarpine, on the ground of its being a depressant to the heart, I have met by the addition of aromatic stimulants, and in one or two cases, of digitalis. I aimed to have each dose absorbed in a little less than one hour, delaying absorption (if the stomach was empty) by having it diluted with a small quantity of hot water or tea, in order to avoid a too suddenly violent effect and attendant dangers; and for this reason also I have preferred the extract to the active principle. In very weak persons, and in those afflicted with fatty or valvular disease of the heart, the remedy in efficient doses is undoubtedly dangerous.

I have ventured to bring the remedy to the notice of the readers of the MEDICAL RECORD with some diffidence, as the number of cases on which the report rests is too small to convince even myself, but there is enough encouragement in the results observed to warrant a trial on a larger scale by those who enjoy more extended opportunities.

Registration of Midwives.—Efforts are being made in England for the proper education and registration of midwives. If the laws now pending are passed they will receive a thorough course of instruction, both didactic and clinical, receive diplomas, and be subject to punishment for malpractice.

POST-MORTEM CÆSAREAN SECTION.

By T. A. O'CALLAGHAN, M.D.,
WORCESTER, MASS.

Mrs. K— —, a multipara, aged thirty-six, had reached about the twenty-eighth week of pregnancy.

Some months before, symptoms had appeared which pointed to a serious organic trouble, and her physician had diagnosed cancer of the stomach. For weeks Mrs. K——'s sufferings had been terrible, so that she took daily from three to four grains of morphine, either by mouth or hypodermically, and this with only partial relief. During this time she was undergoing a slow process of starvation, so that, as death approached, she was almost a skeleton. In her moments of consciousness she said she felt the movements of the child, and, as she was a Catholic, desired earnestly that her child should receive the rite of baptism, and had made her husband and friends promise that an effort should be made in this direction.

Her medical attendant giving little or no encouragement, I was hastily summoned, and reached the woman's side about twenty minutes before her death. She was unconscious, breathing at long intervals, a pulse scarcely perceptible, and bloody froth issuing from her mouth. Her husband and a Catholic clergyman stood beside the bed, who told me of the promise given the dying woman, and of their wish that I should make the effort to save the child. I listened carefully for the fœtal heart, but was unable to detect any sound, so I had little to make me hope, save the last conscious words of the woman (spoken about half an hour before my arrival), that she felt life.

There was no time to call for assistance, or even send for instruments, but as I had my pocket case at hand, I decided to act. The patient's gasps came at longer intervals, and finally ceased, the pulse was lost, and the woman was apparently dead. I waited a few seconds and then, as there were no signs of life, began my work. I made a free incision from the umbilicus to the symphysis pubis, directly in the middle line. The abdominal parietes were so wasted that the uterus was at once exposed. Taking care that no part of the fœtus was near, I plunged the point of my scalpel into the womb. This was in a state of contraction, and on removing my knife, the fœtal waters gushed forth. With my fingers as a guide, I made an opening in the womb to correspond with that in the abdomen, and then without difficulty drew forth a small living child, who at once began to cry feebly. Tying the cord, I handed the babe to the nurse, and gave my attention to the uterus. The internal os was tightly closed, the placenta attached to the left side. The organ continued its contractions as strongly as after a normal birth, and was soon reduced to the size of the double fist, pressing out every drop of water and a considerable quantity of clotted blood.

Running my hand toward the stomach, I found the pyloric orifice one mass of cancerous tissue, and scattered through the intestines and mesentery several small masses of equal density. An external examination showed many small nodules about the size of a walnut on different parts of the body, particularly numerous on the breasts.

The child, a weak, puny little thing, not fully seven months, was baptized and lived three hours.

The duty of the physician is to save life when possible, and the success attending this case, which seemed so hopeless (because of the fearful agony the mother endured, the large quantity of morphine consumed, and the gradual wasting process she was obliged to undergo), should stimulate us to perform post mortem Cæsarean section in other cases which are far more favorable to the preservation of fœtal life.

L'Univers Médical.—A new journal, with the title *L'Univers Médical*, is about to appear in Paris, under the editorship of Dr. Séxéno, a pupil of Dr. Apostoli.

THE CALOMEL HABIT.

By J. T. HENRY, M.D.,
CHESTER, S. C.

In many sections of the South calomel is one of the most frequently used of household remedies, and has been so for a long time. In fact, it is given (by the laity) for almost everything, from a toothache to an ingrowing toe-nail. Hence, there would be nothing more reasonable than to expect some bad results to follow this indiscriminate and too frequent use of so powerful a drug as calomel. While there is rarely to be found chronic mercurial poisoning, there are many who might be said to be victims of "the calomel habit."

These persons rarely present themselves to the physician to be treated for this habit, but come under our observation suffering from other troubles, and their history develops the fact that they have been habitual calomel takers for years. They may tell you that they used to take calomel, but lately have found a substitute in the "Jones" or "Smith" pill, as the case may be; which, on investigation, is found to contain more or less calomel. They all say they take the drug or the pills "for their liver." And will give you almost the following array of symptoms:

"Every few weeks I have headache, cold and clammy feet and hands, sometimes the cold more marked in the tops of the feet than the soles; eat plenty, but do not relish the food; have a full feeling almost all the time; drowsy, but do not rest well at night; have bad taste in the mouth, especially in the morning; sometimes nosebleed; bowels may be constipated or regular; urine more or less scanty and high-colored; mind sluggish; sometimes night-sweats and swimming in the head; also a mean, heavy, creepy, indescribable feeling."

All these persons are more or less anæmic, though not emaciated, and some are even stout. In those whom I have examined the liver or spleen did not seem abnormal. Urine negative. I do not know whether they had any abnormal temperature or not, never seeing the patient during the attack.

When these patients feel the above trouble coming on, they take a dose of calomel, and, to use their own expression, "feel like a new person for a few weeks."

I have tried various other cathartics as a substitute for this calomel, but without effect beyond purging; and I have never known a full dose of calomel to fail to relieve all the symptoms. I have talked with older practitioners on the subject; some of them attribute the above symptoms to a "kind of malaria," and usually prescribe calomel (there it is again), followed by quinine, as they say with good results. These patients, though they may have been taking calomel more or less all their lives, cannot definitely say when the above symptoms began to show themselves. Assuming that their trouble is due to the calomel habit, where are the pathological conditions arising therefrom likely to be found? and what are they? Since my facilities in such research are limited to clinical observation, I shall expectantly refer these problems to more fortunate and more competent investigators, hoping to be either soon convinced of my error, or further enlightened.

Bromidrosis of the Feet.—Scott recommends the following:

℞. Biborate of sodium, }
Salicylic acid..... } āā 2 drachms.
Boric acid..... 30 grains.
Glycerin, at 86 F., }
Alcohol..... } āā 1 ounce.

Mix, and use as a wash three times a day.

This application is particularly useful in those cases where much maceration of the skin is present, and where remedies of other kinds have failed.—*Medical News.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 2, 1891.

THE CAUSE OF DEATH IN DIPHTHERIA.

BESIDES mechanical obstruction, death occurs by four distinct methods in diphtheria. These are considered at length in the *Gazette des Hôpitaux*, in an able and most interesting paper by Dr. Paul Huguenin. General poisoning, similar in its manifestations to the effect of a concentrated solution of some vegetable alkaloid like atropine or aconitine, may result fatally in five or six days. A more common cause of death in diphtheria is broncho-pneumonia, nearly one-half of the fatal cases succumbing to this complication, which is also the cause of death in three fourths of all fatal cases of pseudo-membranous laryngitis. Sudden death in diphtheria is due to infectious myocarditis or to bulbar paralysis.

Diphtheritic broncho-pneumonia appears toward the fourth or fifth day of illness, and causes death by atelectasis and obstruction of the alveoli; in other words, by asphyxia. It presents the clinical aspect of other secondary broncho-pneumonias. Characteristics that are somewhat special are these: Double broncho-pneumonia, pronounced atelectasis, and frequently hemorrhagic and blackish hepatized areas containing purulent spaces, together with lobular abscesses exuding some discharge. The bronchial tubes and alveoli are nearly always filled with fibrinous exudate, more or less liquid in consistency, and containing but few leucocytes. Apoplexies into the parenchyma, so frequent according to Millard, Peter, Bouchut, Labadie, Lagrave, Sanné, and Balzer, are particularly numerous in the posterior inferior portion of the lung. Hæmatosis is incomplete, owing to the inactivity of a large number of the alveoli, and the blood that is already surcharged with diphtheritic poison, carries to various tissues of the body nothing but noxious elements and dissolution.

Death by general diphtheritic intoxication is rare except during epidemics of diphtheria. The ravages of the disease then are lightning-like, similar to the sudden violence of Asiatic cholera. The urine contains large quantities of albumin, indican, and urobilin.

The blood is dark, thick, and the number of white corpuscles increased. There is enlargement and softening of the spleen, hypostatic pulmonary congestion, and slight congestion of the kidneys. In the typical case cited by the author no diphtheritic membrane existed in the larynx, though the hard palate, uvula, soft palate, the pillars of the fauces, and the nasal cavities were covered with thick, gray, irregular patches of exudate that gave a fetid odor to the breath.

The third way in which death occurs in diphtheria is through degeneration of the heart-muscle and valvular endocarditis. About twenty per cent. of fatal cases are due to this cause. The heart trouble does not set in early. It is a complication arising when convalescence seems to be established, though in children it may appear in four of five days after the onset of the disease, and collapse come on rapidly. There is a slight but scarcely noticeable recrudescence of fever, albuminous urine, and a slight systolic murmur due to functional insufficiency. These symptoms are followed by one of great clinical significance, *precordial pain*, just behind the sternum, and nearly on the median line. It bears some resemblance to angina pectoris, and has been compared to the feeling of an iron hand clutching and tearing the heart. Temperature is about normal or slightly subnormal. The uvula becomes paralyzed and fluids are ejected through the nose. The pulse-beats gradually lessen until there are perhaps thirty or thirty five only in a minute. The heart intermits occasionally, acting as if digitalisized, to use the expressive term employed by Traube and Potain. Lesions that an autopsy reveals are purely histological, with the exception of ecchymoses upon the anterior surface and apex of the heart not due to any pericardiac inflammation, dilatation of the organ, and the frequent presence of cardiac thrombus. Muscular fibres, connective tissue, vessels, and in fact every element of the myocardium, are invaded by the process of degeneration. The muscular fibre is friable, swollen, and highly granular here and there, with areas of granulo-fatty degeneration sometimes interspersed at intervals. Connective tissue presents the inflammatory lesions of proliferation and sclerosis. Giant cells abound, and fatty granulations take the place of the last vestiges of atrophied muscle-fibre. Diphtheritic myocarditis is at once parenchymatous and interstitial. The vessels, especially the small arteries, are the seat of "obliterating endarteritis" characterized by an accumulation of embryonic elements about the capillaries, and especially by an enormous thickening of the lining endothelium. The middle coat of the artery practically escapes, but the outer is profoundly affected. Thrombi are found within the walls of the left ventricle near the apex, and about the chordæ tendineæ of the mitral valve. In diphtheritic myocarditis, muscular tissue and the vessels suffer more than connective tissue, which renders the prognosis graver than in other forms of infectious myocarditis; for the heart may become paralyzed before the muscular fibres have time to undergo repair. Many instances during life of so-called peripheral or bulbar diphtheritic paralysis, are found post mortem to be cases of acute general myocarditis. Leyden has examined the cardiac nerves many times where death has been caused by myocarditis, and found t-em normal in every particular. The pathogenesis of diphtheritic myocarditis is as yet obscure. Death occurs from a stopping of the heart that is due to atrophy of muscular fibre.

While neuritis and myelitis of diphtheritic origin are generally recognized, fatal forms of visceral paralysis due to diphtheritic poison are comparatively rare, occurring only in two or three out of every hundred fatal cases.

Localized paralysis may cause death slowly through inanition, or suddenly by entrance of food into the larynx, or by paralysis of the diaphragm. There is partial or total abolition of knee-jerk in spinal cord implication, and attacks of aphasia and amnesia when the lesion is cerebral. Clinically, it is often very difficult to distinguish the symptoms of myocarditis from those of a bulbar paralysis. In myocarditis these symptoms are prominent: Soft pulse, insufficient cardiac contraction, muffled heart-sounds arythmia, dilatation of the heart, early appearance of syncope without much asphyxia, and intensity of collapse. In bulbar paralysis there are present excessive dyspnœa, asphyxia, polyuria, together with localized paralysis of the uvula, larynx, eyelid, of accommodation, and of the limbs. Macroscopically, the lesions post mortem are rarely well defined. The blood is dark, viscid, and toxic. There is softening of the spleen, some congestion of the liver and kidneys, slight inflammation of the pleura, and the serous membranes of the nervous system found filled with fluid. The histological researches of Charcot, Lépine, and Déjerine reveal a subacute myelitis implicating the gray matter on a level with the anterior horns. The nerve-cells are bright, nerve-fibres have disappeared, there is increase in anastomotic prolongations, and the vascularity is intense. The nerve-tubes assume a globular form, they are without myeline, and degenerate. These spinal lesions account for peripheral degeneration in the form of descending neuritis, owing to the destruction of nutritive centres. When bulbar paralysis exists the same lesions are found about the seat of origin of mixed nerves. Often there are hemorrhagic spots along the tract of the peduncular white fibres. Mendel attributes sudden death in diphtheria to hemorrhages of the nerve-centres. While this is not always the case, it is true that this particular mechanism is often the cause of death.

WHO OWNS THE PRESCRIPTION?

The *British Medical Journal* says that the question of the ownership of prescriptions has been settled by law in New York, Massachusetts, and a few other States. In all the cases it has been decided that the druggist is the owner of the prescription. The following is the text of a judicial pronouncement lately delivered on the subject: "The question before the Court appears to be simple indeed. A patient applies to a physician and receives from him certain advice for which he tenders a fee. The physician hands a piece of paper to the patient, purporting to be a written order for certain goods called drugs, which order is filled by a merchant or apothecary. The payment of the fee and the delivery of the goods or drugs terminates the verbal contract, and the druggist keeps the prescription as an evidence that the contract has been fulfilled so far as he is concerned. The druggist can, if he so please, on his own responsibility renew the drugs, for he is but a merchant, and has a perfect right to sell drugs to anyone and in any shape. He need not keep the prescription, nor is he bound to give a copy; but should error occur, he has no protection in case of suit." It is said that some time ago a decision in the same sense was given by the judge of a court in Berlin.

The *Journal* adds in comment on the above: The opinion here quoted does not seem to be sound; the patient receives the prescription in return for the fee which he gives to the physician, but he is under no obligation to give up the prescription to the druggist. He is bound to show it to him, or else he cannot get the drugs he wants, but the document belongs to the patient, who could if he chose enforce its return by action. A publisher might as well claim to keep an author's manuscript as evidence that he had correctly printed it, as a druggist to keep the prescription as evidence that he had fulfilled his contract to supply the drugs ordered of him. Such a claim on the part of a tradesman against his customer is not recognized as valid by English law, whatever may be laid down by the courts of other countries.

In a paper recently read by Mr. Joseph England before the Philadelphia College of Pharmacy, this question of ownership was discussed, the writer taking decided ground in favor of the druggist being owner of the prescription. He cited a long legal opinion furnished by an experienced lawyer, Mr. R. C. McMurtrie, in support of his view.

If the patient is the owner, says Mr. McMurtrie, "he may at any time within six years demand the paper, and if it is not surrendered, sue as for a tortious conversion of his property. If he can't do this he certainly has no title." Various instances are cited also showing the necessity to the druggist of owning and keeping the prescriptions.

AN AMERICAN MEDICAL TEMPERANCE SOCIETY.

A British Medical Temperance Association was organized in 1876. It has now over five hundred members, and has done excellent moral and hygienic work. Dr. N. S. Davis, of Chicago, proposes to organize an American Medical Temperance Society, and he announces that if medical men will send him their addresses he will provide a time and place for their meeting and organization at Washington during the week of the next annual meeting of the American Medical Association. The temperance movement has always had many more active supporters in America than elsewhere, and we have no doubt that Dr. Davis can easily succeed in his very desirable project.

NEW "CURES" FOR CANCER.

Several years ago Dr. J. Mortimer Granville announced, in the *Lancet*, that he had devised a method by which he hoped to cure some cases of cancer at least. He now, in a recent issue (April 4th), renews his statements upon this point, and adds that several patients have been cured. He unfortunately does not give the technique of his method, but says that it consists in the internal use of periodo-hydro-methyloxy chinolin (a substance resembling thallin) and the local injection of papain.

Professor Adamkiewicz, of Cracow, has recently announced that he has also discovered a method of successfully treating cancer. His method has been tried in three cases of epithelioma of the lip in the clinics of Professors Obalinski and Korezynski, and, although sufficient time has not yet elapsed to allow of a definite judgment being formed as to its value, the effects have been suffi-

ciently remarkable, in his opinion, to justify further trial. The size of the growth has been markedly diminished, and the enlarged glands in relation therewith have become much smaller; even "entire disappearance" is spoken of. Coincidently with these local effects the patients have gained weight.

Professor Mikulicz, of Vienna, has found that good results have been obtained in cancer by the use of pyoktanin; and the "dyeing" method has also been found to be apparently useful by several surgeons in this city.

Dr. Inglis Parsons still asserts that strong galvanic currents arrest, and perhaps cure, some cases of cancer.

Dr. George Dean has apparently proved that Russell's micro-organism of cancer is not a micro-organism and not characteristic of cancer (*Lancet*, April 4th), but this bacteriological set-back does not at all interfere with the present "boom" in cancer cures.

ANTISEPTICS IN RHYME.

If we are not greatly mistaken, that eminent poet and builder of lofty and sustained iambics, Dr. G. M. Deney, of Keytesville, Mo., has undergone a change of heart. Not long ago he was bitterly epigrammatic and antagonistic to all forms of microbes and all the conclusions of microbic pathology. In a more recent contribution to rhyme and surgery, however (*Journal of the National Association of Railway Surgeons*), in a truly scientific spirit, he admits the bacteria and poetizes antiseptics in a most helpful manner.

We cannot give our readers all of the poem, but it would be unkind to deny them the truly Hudibrasian description of the way in which the surgeon should prepare for an operation. Dr. Deney says, and truly:

"Although in details we may vary,
Some plan is necessary,
To heal a wound by first intention.
Some needful rules I here will mention.
The surgeon first his clothes should doff,
His coat and vest and shirt pull off.
In rubber apron should be drest,
Extending from the feet to chest.
Scrub well his hands with soap and water,
If he don't he ort'r.
The patient sponged 'till all is sweet,
Is laid upon a rubber sheet.
The towels all on chairs are hung,
And water by the waiter brung.
As vicious germs will always breed,
Some antiseptic he will need.
As bichloride is dangerous stuff,
One in two-thousand is enough.
Carbolic acid one one-thirty,
Will keep the knives from getting dirty."

There is assuredly an undercurrent of truth and sense in the foregoing, and we feel sure that Dr. Deney is an informed, intelligent, and successful practitioner; but we consider that his recommendation that the surgeon should take off his clothes before operating as both radical and indelicate. Even the suggestion that he pull off his shirt seems to be carrying things too far, especially in institutions where co-education prevails. Nothing could be neater or more forcible, however, than the injunction to

"Scrub well the hands with soap and water,
If he don't he ort'r."

Such maxims have more than a surgical and technical value. They can be taken to heart by the whole human race, which should turn its face gratefully toward Keytesville, Mo.

A final word of caution is given by Our Poet against the practice of interfering with dressings after they are once applied.

"When once a wound is dressed
It must be left at rest,"

a sentence which contains both rhyme and reason, besides being orthographically correct. This point is further emphasized:

"Success alone inures to he
Who never yearns the wound to see.
The cortege of a med'ling ape
Are hearses, obsequies, and crape."

We can well forgive the slight dislocation of grammar in the above for the sake of the important lesson that is taught.

We join the Muse of Song in tendering to Dr. Deney the assurances of our distinguished consideration. Long may he cut and sing.

A NEW TYPE OF SPINAL DISEASE.

An article in the *Journal of Nervous and Mental Diseases* for March, 1889, by Dr. J. J. Putnam, and one in the April issue of the same journal, by Dr. C. L. Dana, furnish material, it is thought, for a new type of spinal disease. This new type belongs to the class of progressive degenerative diseases, such as locomotor ataxia and the other scleroses. In it the cord is affected with a "combined sclerosis" of the lateral and posterior columns. This sclerosis runs a somewhat rapid course, and is associated finally with a softening of certain levels. Some years ago Dr. Gowers, of London, described a disease which he named "ataxic paraplegia," in which there is also a combined sclerosis of the lateral and posterior columns; but this is a very chronic disorder, and in most cases is only a modification of locomotor ataxia.

The new type of spinal cord disease of Putnam and Dana is stated to be different, both clinically and pathologically, from ataxic paraplegia, hereditary ataxia, and other forms of combined system diseases of the spinal cord. The symptoms are summarized by Dr. Dana as follows:

The disease begins generally with numbness of the extremities, followed by progressive enfeeblement. Great emaciation and anæmia are present, and there is often an obstinate diarrhœa. No paralysis of any special groups of muscles occurs, but there is a progressive weakness, and finally paraplegia sets in.

There are in some cases anæsthesia and ataxia, but spastic symptoms with exaggerated knee-jerk and ankle-clonus are the more common.

Lancinating or girdle pains are very rarely present.

The arms are affected, but less than the legs. The vision and other special senses and speech are not disturbed. Mental symptoms approaching dementia were observed in the terminal stage in one case.

The general course is that of a rather rapidly progressive affection, causing numbness and sometimes anæsthesia of the extremities, especially the lower, with progres

sive weakness of the extremities. This is associated with anæmia, general muscular emaciation, and diarrhœa, the disease ending in a paraplegia and death from exhaustion.

The course of the malady is relatively rapid, averaging two years.

A peculiarity of it seems to be that it affects women oftener than men, and also that it occurs after middle life. In these respects, as well as in its subacute course, it differs from such diseases as locomotor ataxia or lateral sclerosis.

The cause of the trouble is not certainly determined. It does not seem to be due to syphilis or alcoholism. The patients had, however, an extreme anæmia in most cases, and also a natural or acquired neurotic constitution. Lead-poisoning is suggested as one factor.

The disease is one which is probably rare, but which, if observed by others heretofore, has probably been diagnosticated as myelitis or multiple neuritis. It is not, however, an inflammatory disease in any sense, and it can, we are told, be usually distinguished from the diseases mentioned as well as other types.

On account of the difference in prognosis and treatment, a diagnosis of such cases is greatly to be desired.

Treatment has heretofore been futile, though temporary improvement may occur under iron and roborant measures. Possibly an early recognition of the malady might enable one to stay its course.

CHEAP DOCTORS.

The American degree of doctor of medicine is too cheap. So thinks John H. Rauch, M.D., the able secretary of the Illinois Board of Health. Excepting Belgium this is the only country in the world where the license to practise and the M.D. degree can be obtained with only three years' study. Even could American students learn more rapidly than foreigners, as is often asserted, the former's preliminary education is so much inferior to the latter's that such an assertion applied to medical students becomes erroneous. With many American students the habit of application and of scientific and logical thought is not formed until the medical college is entered. The American degree is also cheap in a pecuniary sense. Here are some of Dr. Rauch's statistics and sensible deductions.

The average fees for the eleven London schools are, exclusive of the examination fees, £118 5*s.*; for the provincial schools £98. In addition, each student has to pay from 10*s.* to £5 matriculation to one of the degree-granting bodies; from £1 to £15 for the first examination; from £1 to £10 for the second; from £2 to £15 for the first degree or qualification examination, and from £5 to £15 for the second qualification examination. In some of the colleges in the United States all the fees do not amount to $200, and in at least one the whole course of study and the diploma can be had for $138. A careful study of the systems of education in foreign countries shows that a large part of the time and much of the money are spent in acquiring practical knowledge of medicine by actual work in hospitals, and this work is tested by practical examinations, such as are too infrequent in this country. Too often the American graduate attends his first case of labor after he begins practice. Such is not the case abroad. The same is true of other conditions that physicians and surgeons are called upon to treat. The defects in the American system of medical education, then, are: 1. Too little preliminary education, and thus a lack of ability to grasp scientific principles. 2. Too much didactic work by the teachers. 3. Too little clinical work by the students. 4. Too few tests of practical work. 5. Too short a time of actual work and study. Increasing the preliminary qualifications and lengthening the time of study will remedy the other defects, and will kill off the useless and low-class schools.

News of the Week.

The American Medical Association.—As has been previously announced, the forty-second annual meeting of the American Medical Association will be held in Washington, D. C., on Tuesday, Wednesday, Thursday, and Friday, May 5th, 6th, 7th, and 8th, the first general session being opened at 11 A.M. The general addresses will be as follows: Medicine, Dr. E. L. Shurley, of Detroit, Mich.; Surgery, Dr. Joseph M. Matthews, of Louisville, Ky.; State Medicine, Dr. W. L. Schenck, of Topeka, Kan. Among the questions that will be brought to the consideration of the delegates will be the change of the day of meeting; the abolition of the committee on State medicine; the formation of a section on dietetics and physiology; the granting to permanent members all the rights of delegates; the recognition of all State and district societies, affiliated to the Association and having a membership of one hundred or more, as branches of the American Medical Association, as a result of which the members of such societies will enjoy all the rights and privileges of delegates; and finally, the removal of the publication office of the *Journal* from Chicago to Washington.

Carl Rudolph Braun, Professor of Obstetrics and Gynecology in the University of Vienna, etc., died March 28th, aged sixty-nine years. Carl Braun graduated in Vienna in 1847, and after a short time spent in the pathological laboratory became assistant in obstetrics under Klein. In 1853 he was called to the Tyrol as professor, where he, in 1857, published his text-book of obstetrics At about this time, after declining the chair at Zurich and at Pavia, he came back to Vienna, on the death of Klein, as professor of the obstetrical clinic, and at the same time devoted himself to the establishment of a gynecological clinic in connection with the lying-in department. From this time until his death Braun has been one of the most prominent figures in the medical life of Vienna, and in obstetrics has attained a world-wide reputation.

A Pan-American Medical Congress.—It is proposed that an International American Medical Congress be held in Chicago at the time of the Columbian Fair.

Major Alfred A. Woodhull, Surgeon U. S. A., is detailed to represent the Medical Department of the Army at the International Congress of Hygiene and Demography at its meeting in London, England, from August 10 to 17, 1891.

The Memphis Hospital Medical College held its annual commencement March 27th, and graduated a class of eighty-nine.

Dr. Paul H. Kretzschmar, Supervisor at Large of Kings County, died suddenly on April 27th at his home, 402 Washington Avenue, Brooklyn. His death was due to Bright's disease, but it was hastened by an attack of the grip. The dead official was born in Dresden in 1847. Subsequently he was graduated from the University of Berlin, and came to this country in 1869. He married here and opened a drug store in 1872. While engaged in that business he studied medicine at the Long Island College Hospital, and became a physician in 1877. He built up a profitable practice. Dr. Kretzschmar entered politics in 1884 as a Cleveland Democrat. He was one of the organizers of the Young Men's Democratic Club. Socially Dr. Kretzschmar was very popular, and was a member of the Oxford, Brooklyn, Hanover, Germania, Constitution, and German Press Clubs.

The American Medical Editors will meet at Washington on May 4th, and discuss the report of the committee upon the following questions: "What has been the real effect of the rapid increase of free hospitals and dispensaries in all the large cities, ostensibly for the care and treatment of the sick poor, during the last twenty-five or thirty years; first, upon the poor, and second, upon the people as a whole? What has been the effect upon the real medical interest of the medical profession? What are the duties of those controlling the medical press relating to the foregoing questions?"

Dr. Richard Gundry, Superintendent of the Maryland Hospital for the Insane at Spring Grove, Baltimore, died at that institution on April 23d. His death was caused by Bright's disease and complications. Dr. Gundry was one of the best known experts in diseases of the mind in this country. He was born at Hampstead, near London, England, in 1829, and was educated in a private school at Hampstead. He came to America in 1845 and studied medicine at Simcoe, in Ontario, with Dr. Charles W. Covernton. Entering Harvard College, he took all the honors, and was graduated from the medical department in February, 1851. He then removed to Rochester, N. Y., where he practised medicine until 1854, when he removed to Columbus, O. He entered the Ohio Lunatic Asylum in the year following as assistant physician.

Women Physicians and the Liquor Business.—At the annual dinner of the Alumnæ Association of the Woman's Medical College and Hospital last week, a move was made toward securing for women the right to vote for Excise Commissioners in New York. About eighty women practitioners were present. Dr. Julia E. Bradner, of Middletown, Orange County, gave an address on "Woman in the Medical Profession," in which she opened the subject. She said, closing her address: "Let us never forget that the woman physician represents the pioneer woman in a pioneer government, and if our country is to continue a model republic its women must represent the highest type of women. Napoleon said: 'The future destiny of the child is always the work of its mother,' and we women physicians demand of the State of New York that it grant its women the same voice in the health and morals of its children that they already have in their education; that the women who are privileged to vote for School Commissioners be also allowed to vote for Excise Commissioners. We do not ask it in the interest of universal suffrage, prohibition, or of either political party. We ask, rather, that it be removed entirely from politics. We ask it as women in the name of the mothers, wives, sisters, and daughters, and as physicians, knowing that its rum-soaked children are the very incubators of disease. Surely, the Empire State will be safe if it trusts the health and morals, as well as the education, of its children to women."

The Massachusetts Medical Registration Bill has failed to pass. The opposition to the bill, according to the *Boston Medical and Surgical Journal*, was based partly on the feeling which had been apparently fomented, that the bill would be in some way of advantage to the Harvard Medical School.

A Proposed International American Medical Congress.—Dr. Charles A. L. Reed, of Cincinnati, purposes introducing at the Washington meeting of the American Medical Association resolutions to the effect that an invitation be issued to the medical profession in the various countries of North and South America, to hold a congress in the United States.

New Medical Colleges in Chicago.—An institution to give instruction in medicine and surgery, to be known as the Illinois School of Medicine, was recently incorporated, with a capital stock of $10,000. The incorporators are physicians. It is said that Chicago is to have a new institution known as the German College of Medicine and Obstetrics, with a capital stock of $50,000. The college will have ten professors, four to teach in the English language and make a specialty of obstetrics; the other professors will teach in German and have charge of the regular college course. Five years of study will be required before a diploma is granted. It is thought that eventually a college building will be erected near Humboldt Park. The money required will be provided by the incorporators, and by the professors who are to occupy the chairs in the college. The professors have not yet been selected.—*Medical News.*

Dallas, Tex., hopes to have a new $100,000 hospital "It is God's work," says the *Texas Health Journal*, but we should judge from the context that the local politicians have a good deal to say about the matter.

Resignation of Dr. Da Costa.—Dr. Da Costa has resigned the chair of Practice of Medicine in Jefferson Medical College. The reason for his resignation, says the *Medical and Surgical Reporter*, is that Dr. Da Costa desires to withdraw from the cares and burdens of the professorial position, in order to have more leisure for his large practice. For twenty-seven years, in one capacity or another, Dr. Da Costa has been identified with the Jefferson Medical College, and it is not too much to say that its present exalted position is, in a large measure, due to the admirable manner in which he fulfilled the duties of his position, and to the lustre of his reputation, which has so effectively supplemented that of Meigs, Gross, Pancoast, and others.

Dr. Charles W. Dulles has resigned the editorship of the *Medical and Surgical Reporter*, which he has ably conducted for the past four years.

The German Surgical Congress was opened in Berlin April 1st. The first two days were devoted chiefly to discussions upon tuberculosis. Bergmann spoke despondently of tuberculin, Koenig was more hopeful, and Schede declared it to be "an invaluable weapon." Senger, of Krefeld, spoke on the efficacy of iodoform injections in surgical tuberculosis. He believes that he has discovered the reason why the treatment of articular tuberculosis with iodoform is sometimes successful and sometimes not. It is not the iodoform itself, he thinks, which causes the cure, but the formic acid produced by its oxidation. If oxidation take place iodoform acts, but not otherwise. On the strength of this theory he has injected formate of soda and formic sulphuric ether with good effect. The last speaker was Dr. Rubenstein, who communicated the results obtained by Professor Schueller, of Berlin, in more than one hundred cases of local tuberculosis of the skin, the glands, the bones, and the joints by a combination of internal treatment with guaiacum, partly with surgical treatment, partly (in tuberculosis of the joints) with injections of iodoform glycerine into the joints and directly into the tubercular soft parts and bones belonging to the joints. Of fifteen cases of articular tuberculosis treated in this manner, nine are already permanently cured. As regards the other forms of local tuberculosis, Schueller's results are of special importance, because in many cases of cure there has been no relapse, though years have passed since the close of the treatment. Some cases have been observed for more than eight years. On the second day Liebreich's treatment by canthardinate of potash was considered and condemned. Among other communications was one by Schuchardt, of Stettin, who reported a case of extirpation of a tubercular kidney, and several cases in which lupus had at first been supposed to be cured and had afterward reappeared, were shown. Urban, of Leipsic, showed a case of extensive lupus of the left temple, cheek, and neck, which had been completely cured by extirpation, followed by transplantation of healthy skin. Dr. Benda showed a case of traumatic cortical epilepsy, which had been cured after extensive osteoplastic trepanning and the removal of a piece of the cerebral cortex. Koenig then spoke on the osteoplastic treatment of congenital dislocation of the hip-joint. He had tried to obtain a permanent cure by splitting off a plate of bone from the pelvis and forming an artificial socket to hold the condyle firmly. He could not report definitely on the result, mainly because two of the children first operated on had died of infectious diseases.

The Kansas City Medical College.—This school did not graduate twenty three students, as was announced in our issue of March 18th. The school has a three-year course, and has been opened but one year; consequently there were no graduates at this time, but there are twenty-three matriculants attending lectures.

The Medical Society of the State of North Carolina will hold its annual meeting at Asheville on May 26, 27, and 28, 1891.

The American Medical College Association will hold its next session at the Arlington Hotel, Washington, on Monday, May 4, 1891, at eight o'clock in the evening.

Medical Assistants in New York State Hospitals for the Insane.—An open competitive examination of candidates for junior assistants and female physicians in the State hospitals for the insane will be held by the State Civil Service Commission, at the Capitol in Albany, June 11th. Candidates must be residents of the State, and must have had one year's hospital experience, or three years' experience in the general practice of medicine.

The Chicago Presbyterian Hospital.—A considerable addition to the present large buildings of the Presbyterian Hospital is being planned, and work will be commenced early. The hospital staff is also being strengthened by the addition of new members. Again, an obstetrical ward is soon to be formed, which will be a valuable adjunct to the institution.

The Influenza in Chicago.—The recent epidemic, which prevailed for a period of about a month or six weeks, and which indirectly produced the highest mortality known in the history of the city, has now very decidedly abated. The police and street railway forces of the city were considerably crippled during the height of the affection. Immense quantities of phenacetine were prescribed, this seeming to be the favorite remedy, and to have in great measure supplanted antipyrine in professional and popular favor.

"The Climatologist" is the name of a new journal which is announced to appear in July of the present year. It will be devoted to a consideration of all questions relating to climatology, mineral springs, diet, preventive medicine, race, occupation, life insurance, and sanitary science. The editors will be Drs. John M. Keating and J. P. Crozer Griffith, of Philadelphia, and Charles F. Gardiner, of Colorado Springs. The editorial office will be located in the latter city.

Another Name for the Influenza.—A physician of this city recently received a note from one of his patients asking him to call, as the writer was "wory seck of the Grab."

The Proceedings of the Tenth International Congress will be distributed to the American members, according to the announcement of a German paper, by the Smithsonian Institute in Washington.

Gift to a Hospital.—George M. Pullman has given to the St. Luke's Hospital, Chicago, what is probably the most complete hospital ward in the world. He gave orders that it should be the best and most beautiful place in the world for sick and crippled children. The ward consists of two rooms, and has accommodation for twenty-two little ones.

Still Another "New Treatment of Tuberculosis."—Medical circles in Paris are greatly interested in a new treatment for tuberculosis discovered by Germain Sée. Professor Sée's treatment requires the patient to pass four or five hours daily in a chamber where his or her entire body, with the exception of the head, is compressed in linen bandages saturated in a solution of creosote. The pressure is then increased until it reaches an atmosphere and a half. Excellent results are already claimed for this alleged "new discovery."

North Carolina State Medical Society.—The thirty-eighth annual meeting of the North Carolina State Medical Society will be held in Asheville, May 26th, 27th, and 28th.

New York Polyclinic.—Dr. Edward A. Ayers has been elected to the Professorship of Obstetrics in the New York Polyclinic.

American Academy of Medicine.—The Sixteenth Annual Meeting of the Academy will be held at the Arlington Hotel, Washington, D. C., on Saturday, May 2, and Monday, May 4, 1891.

The New York College of Pharmacy held its Sixty-first Annual Commencement, at Metropolitan Opera House, Monday evening, April 27th.

Studying Disease in Domestic Animals.—The Board of Regents of the University of Nebraska have called Dr. F. S. Billings to take charge of the work of investigating the diseases of domestic animals, and have appropriated over $10,000 to cover the expenses of the undertaking for the first year. This action was taken at the instance of a committee representing the live-stock interests of the State. Dr. Billings's staff will consist of a chemist and an assistant, the latter to receive a salary of $1,200, and also a corps of volunteer workers. These volunteers will be assigned to original and practical work, the results of which they will be at liberty to publish, and will receive credit for as their own.

Michigan State Medical Society.—The twenty-sixth annual meeting will be held in Saginaw, Mich., Thursday and Friday, June 11, and 12, 1891.

The Medical Association of the State of Alabama.—This Association has just closed an important meeting, held April 14th, 15th, 16th, and 17th, at the city of Huntsville. About one month ago the Medical and Surgical Society of Montgomery sent a circular letter to each County Medical Society in the State, asking that they instruct their delegates to the State Convention to vote for the repeal of a special rule passed by the Association many years ago, prohibiting, in strong terms, consultations with homœopathic and eclectic physicians. The resolution to repeal this ordinance provoked a warm discussion, but it was passed by a two to one vote. The Association still abides by and subscribes to the Code of Ethics of the American Medical Association, but many of its members contend that they are at liberty to consult, under a liberal construction of this Code, with all legal practitioners of good standing, and the repeal of this special iron-clad State ordinance is supposed to have been passed to allow such individual members as desire to exercise their discretion in the matter of consultations to do so. The following officers were elected for the ensuing year: *President*, Dr. B. J. Baldwin, of Montgomery; *Senior Vice-President*, Dr. W. C. Wheeler, of Huntsville; *Junior Vice-President*, Dr. J. Huggins, of Newberne; *Orator*. Dr. B. L. Wyman, of Birmingham; *Members of the State Board of Health for Five Years*, Drs. Peter Bryce and James Searcy, of Tuscaloosa; *Treasurer*, Dr. W. C. Jackson, of Montgomery; *Secretary*, Dr. T. H. Means, of Montgomery. Next place of meeting, Montgomery.

Death of Dr. J. H. Ward.—Dr. James Henry Ward, of Brooklyn, died on Wednesday, April 15th, of cerebral hemorrhage, at the age of sixty-seven. He was graduated from the New York University of Medicine in 1848, and after practising a few years he went to Berlin, and under Professors Virchow and von Langenbeck studied pathology and histology, and returning to Brooklyn again, commenced general practice, in which he was actively engaged up to the day of his death. From the humblest beginning he rose by his own unaided efforts to the position of the most prominent physician in the Eastern District of Brooklyn. He was an able practitioner, an admirable teacher, a helpful consultant, and a most profound scholar. To a well-cultivated mind he added a kindness of manner and a sympathy in the very expression of his face that gave hope to his patients, and inspired confidence in their friends. A character too noble to indulge prejudice or gratify jealousy, he leaves no one to speak ill of him. The influence of a well-spent life will not die with him. As a practitioner of medicine he was noted for his scientific attainments, cheerful disposition, and affectionate consideration for the younger struggling members of his profession.

The Corner Stone of the Langenbeck House, in Berlin, was laid on April 4th, in the presence of representatives of the Emperor, the German Surgical Society, and the Berlin Medical Society, and of many of the members of these societies. The address was made by Dr. Thiersch, President of the Twentieth Congress of the German Surgical Society. In the stone were enclosed the deed of foundation, volumes of the Proceedings of the German Surgical Society, and of the Berlin Medical Society, for 1890, a copy of the Langenbeck memorial oration, delivered on April 3, 1888, by Dr. von Bergmann, the copy of a pamphlet entitled "Die letzte Stiftung der Kaiserin Augusta," and a picture of Langenbeck.

"Preshure of the Bowls upon the Womb."—The following medical opinion upon an applicant for life insurance was received a few days ago by one of the New York companies from an out-of-town examiner: "I find the abdominal mustels relaxed, so much so that they allow the bowls to fall low in the pelvis, and by so give preshure upon the womb, rectum and by the presher, imped the free flow from the femeral vein &c &c now by this relaxation of the abdominal mustels of corse the upper organs are unsupported aspetialy on the right side such as liver and right lung. This giving an allgone fealing &c. I am speaking of Mrs. Nelly D——."

Death of Dr. Philip Leidy of Philadelphia.—Dr. Philip Leidy, ex-port physician and a well-known practitioner, died at his home in Philadelphia, April 29th, of pneumonia, aged fifty-three. Dr. Leidy was a brother of the eminent physician and naturalist, Dr. Joseph Leidy, who now lies dangerously ill and who is not expected to survive. Dr. Leidy was a member and ex-President of the Medico-Chirurgical Society, and also a member of the Northern, Philadelphia County, and State Medical societies, and of the American Medical Association. He was the author of various reports to the Medical and Surgical Department of the United States Army, and of papers read before medical societies, and has made valuable contributions in other ways to medical literature.

Clinical Department.

A CASE OF ACONITE POISONING.

By M. A. WARRINER, M.D.,
BRIDGEPORT, CONN.

Mr. G. N ——, American, aged sixty, by occupation a stable-keeper, hurriedly entered my office, December 19, 1890, at 9.10 P.M., saying that he had taken some tincture of aconite by mistake some ten or fifteen minutes before. I subsequently learned that he had taken it at 8.40 P.M. He had felt no tingling or numbness of the extremities. Pulse full and 80 to 85 per minute. As is too frequently the case, two bottles of medicine had been set side by side, one a bottle of cough syrup for himself, the other the bottle of tincture of aconite which he had been giving to his horses. Just before starting for home he had hurriedly taken up one of the bottles and poured down two good swallows, when he discovered his mistake. As near as could be told by parties who had noticed the bottle before he took it, at least four teaspoonfuls were taken. He first went to a drug store near by, where two or three ineffectual attempts were made to excite vomiting. When he arrived at my office I immediately gave him about fifteen grains of sulphate of copper and two glasses of lukewarm water. He vomited in five or six minutes, so that I did not use a stomach-tube. He vomited a large amount, no less than two quarts, and probably more. Immediately after vomiting he began to feel the characteristic numbness and tingling. The tingling began in his tongue, then the lips were affected, and it rapidly spread backward and downward till the whole region of the lower jaw was affected, then extended upward on to the face and cheeks. Said his face "felt terribly drawn." He began to feel the tingling at the finger-tips at the same time that the face was affected. As soon as the stomach would retain it, I gave him 15 minims tincture digitalis in an ounce of wine. After he had vomited and the tingling began, he complained of being intensely cold. At 9.40 he got into his buggy and drove me to his house, which was only a short distance. I had him go to bed at once, and hot bottles were packed around him and plenty of blankets over him. He was given some hot whiskey, which was soon vomited. He was then given between two and three ounces of whiskey per rectum. As his pulse grew gradually weaker, I began to give whiskey hypodermically. About 10.30 he complained of not being able to see, and had two tonic convulsions. By this time the pulse had become imperceptible at the wrist, and Dr. Blodget was called in consultation. Hypodermics of whiskey were continued. The bowels began to move rapidly, but he was not allowed to sit up or raise his head to vomit, which he attempted several times. About 11 o'clock the pulse was barely perceptible, but under the use of hypodermics of whiskey it soon improved, but was very irregular. At 11.30, $\frac{1}{60}$ gr. digitalin was injected. At 12 the pulse was very much improved, but as the breathing was not good, $\frac{1}{15}$ gr. sulph. strychnine was given, which soon remedied that. He fell into a calm sleep, and at 2 A.M. was given more whiskey under the skin, and was not disturbed again till morning, when he announced himself as feeling very comfortable. That day the bowels continued loose, and all he complained of was being sore from the numerous punctures of the hypodermic needle. His recovery was uninterrupted, and in a few days he was out about his business.

The poison was in his stomach thirty five minutes. He took at least four teaspoonfuls, but absorption was delayed on account of his stomach being full. Under the circumstances, perhaps it would have been better to have made him remain at the office instead of allowing him to go home, but as he had not felt any tingling until after vomiting, and as he thought he had not had the poison down more than fifteen minutes, I did not realize how much had been absorbed, as the pulse was in good condition when he went from the office. In another similar case I would give the digitalin and strychnine hypodermically as soon as the stomach was emptied.

A CASE OF RABIES.

By M. W. KELLIHER, M.D.,
PAWTUCKET, R. I.

Daniel M——, a strong, vigorous man, junk dealer, was bitten by an unknown dog May 14, 1890. The wound produced by the bite was cauterized about four hours after the accident. The man paid no further attention to the matter, never suspecting that the dog had rabies. His health was as good as usual until the morning of July 23, 1890, when at breakfast he noticed that it was with difficulty he drank coffee. I saw him at 5 P.M. of that day, when he complained of pains in his back, neck, and epigastrium, and constriction of the chest. His expression was anxious, but his appetite was good. He had been troubled with constipation for three or four days. He ate breakfast well enough, but could take no liquids, because, as he said, they "choked him." This he attributed to a hard day's work the day previous. I asked him to drink some water, and as I handed him the glass he gasped for breath and asked that the water be taken from him. I insisted that he should drink the water, and while swallowing the liquid the pain he endured from the spasmodic action in his throat was intense. He placed one hand on his throat, and the other hand on the back of his neck, and appeared to suffer intensely for several seconds after he had swallowed the water. The man showed no fear of hydrophobia even now, attributing the spasm of the muscles of deglutition to hard work done the past few days. The next morning his deglutition was more embarrassed, and even the sight of water produced dyspnœa. Pulse, 120; temperature slightly elevated; was able to take some solid food, but liquids produced a spasm in the muscles of the throat. He said he was determined to recover, and had no fear of hydrophobia. The morning of the third day of the disease he had a more careworn expression, some dyspnœa, and could not be induced to take or look at water. Pulse, 140; some elevation of temperature. At 4 P.M. of the same day he appeared very delirious, talked incoherently, and wanted to leave the house. He took some water in his mouth, but in swallowing it created a very great spasm of the muscles of the throat. Up to this time he had not slept, though he had been kept under large doses of bromides and chloral from the beginning. Pulse, 150; temperature, 104° F. The bromidia had now been increased to ʒ j. every half hour, in order to produce sleep. After taking it at this rate for about six hours he fell into a sleep and slept six hours, the first since the beginning of the disease. When he awoke was very delirious. Pulse, 150; temperature, 104° F. in the axilla. He was unable to recognize anybody. Would take water in his mouth but was unable to swallow it. Five hours later he became unconscious. Temperature in axilla, 105° F.; pulse, 150, very feeble. At 8 P.M. of the same day, being the fourth day of the disease, the patient was unconscious and had Cheyne-Stokes respiration; pulse more feeble; temperature, 105° F. He gradually grew more exhausted, and died about 11 P.M. of the fourth day.

The peculiar feature about the disease was the absence of convulsions. This I attribute to the constant use of antispasmodics from the beginning. From the first he received a quarter-grain of morphine every two hours. This was later discontinued, and he was given ʒ j. of bromidia every hour, and later still, one grain every half-hour. He was bitten in the night while trying to drive this dog from his hennery. I could not discover to whom the dog belonged, or anything in regard to his history.

ABSCESS OF THE LIVER OF MALARIAL ORIGIN—RECOVERY.

By E. VILLARI, M.D.,

NEW YORK.

In the month of March last I was called to the bedside of a poor Italian, whom I found very emaciated and feverish. He had been complaining for three months of pains in the abdomen, more especially on the right side. I found the hepatic region very painful to the slightest touch, the liver was enlarged in every direction, and a small elevation with deep fluctuation in the posterior axillary line, between the ninth and tenth ribs, with widening of the intercostal spaces of the right side.

The hepatic pain had begun three months before radiating in the right shoulder, and since then the patient had suffered from irregular fever, and from diarrhœa alternating with costiveness. It was only a week before my call that the man had noticed the oval elevation in the right side posteriorly. All the symptoms were those of an abscess of the liver.

The man, before this disease, had suffered only from occasional attacks of fever, beginning with chills and ending with perspiration, evidently malarial fever. After an exploratory puncture, which proved the correctness of the diagnosis of abscess, a large trocar was introduced in the direction of the oval elevation, and about four pints of black pus were evacuated. Dr. Byron, who was present at the operation, kindly examined some of the pus under the microscope and found it to contain hepatic cellules and crystals of cholesterine.

At the end of the operation, and for two days after, the only trouble was a little cough from œdema of the right lung, caused by the relief of the hepatic pressure. A rubber tube was introduced into the opening, and the abscess-cavity was washed out daily with a decoction of powdered cinchona bark, half an ounce in a pint of water. This solution is microbicidal, and it may be used freely without the least fear of evil consequences from absorption, which are apt to follow the employment of so many other poisonous substances when used for a long time. Only for the first two days was washing with solution of bichloride mercury, 1 in 2,000, resorted to. The patient took early each morning a decoction of cinchona, one-sixth of an ounce in a half tumbler of water, and one pill of iodide of iron (Blancard's) was taken before each meal. Diet was milk and soup for the first three weeks; after this meat was added.

At the end of two months the man was completely restored to health, and able to do his usual work of street sweeping without any trouble. As this man never was in a tropical country, never suffered from hemorrhoids, never had any intestinal trouble, nor suffered from gallstone, but presented only the symptoms of malaria, so I must regard malaria as one, and in this case as the only, etiological factor of the abscess of the liver. Malaria is not mentioned by pathological authors as a cause of abscess of the liver, but in this case it seems, for the above-mentioned reasons, to be the true cause.

The complete restoration to health of this man, after such an extensive destruction of the hepatic tissue, proves clinically the reproduction of the hepatic cellules, as was experimentally demonstrated on dogs last year by a German physician, whose name, I regret to say, I do not recollect.

TREATMENT OF HABITUAL CONSTIPATION.

By W. WASHBURN, M.D.,

NEW YORK.

An article on this subject in a recent issue of the Medical Record recalls to mind some very obstinate cases of habitual constipation that have come under my care.

The notes of one of the most long-suffering and in some respects serious cases of mine will illustrate. I was called January 2, 1889, to see Miss A——. I found her in a state of collapse, with cold perspiration and thready pulse; she was extremely pale. Was informed that she had just had a movement of the bowels, the first for five weeks. This was said not to be unusual as to length of time or condition following movement except that now she was "weaker and fainter." Stimulants were given by the mouth, ammonia by inhalation, and hot applications were made to the extremities. The patient soon regained strength and was about as usual. Having been the family physician for a long time I had of course noticed that the patient was of a sallow complexion, and was much troubled with what some of our best skin specialists had been treating for acne, but never, according to the patient, had her bowels been the recipient of the slightest care by them, not even the courtesy of an inquiry as to how they were. The treatment for the acne went on pretty regularly for over two years, as did the treatment of the bowels, periodically, at the hands of now this one and now that, until finally it had been received by the family some time before I knew them as the inevitable, and nothing was done for a long time about the bowels; but, as before stated, the acne received almost constant attention at the hands of one or another specialist. Careful questioning elicted the usual causes for constipation, or at least very common causes—irregular habits as to eating, and in short irregular habits generally, frequent purgation in the early history of the trouble, followed later by purgation when the conditions would no longer permit the bowels to go unmoved, which was usually for the past two years between four and five weeks, with a constant tendency to longer periods between the movements. Hot drinks, as usual, contributed to the general bad results. Careful consideration was given to the diet and the patient's tastes consulted, and a line of diet was laid out comprising the cereals that were best tolerated by the patient, fruits, especially baked apples, cooked peaches and prunes, oranges, etc.

Citrate of magnesia was ordered to be taken half an hour before breakfast, in quantities that would not cause purgation. This was strongly insisted upon, for experience has demonstrated that frequent purgations cause constipation, even in the healthy. A large-sized wine-glass was taken as the first morning draught, with instructions gradually to increase the dose if necessary to produce a movement. The unfortunate tendency to take medicine "to save it" was combated by having the magnesia in siphons, so that it would be perfectly preserved until used. A regular time of day was selected in which to solicit movements. In order to take advantage of the effect of digestion it was ordered that this soliciting should take place half an hour after the noon meal, and that calculation be made to pass urine at this time, as a further aid to the bowels. Exact regularity was insisted upon in this matter, with instructions to persevere from day to day, taking an enema of warm water only every third day if the bowels failed to move without. The patient was told that as heat had a tendency to constipate and cold to move the bowels cold drinks should be chosen. Beer was substituted for tea to a large extent, ice-water was taken in moderation, milk was only to be used very sparingly. Only one injection of water was used, the bowels moving at least as often as on alternate days thereafter. Gradually the quantity of magnesia was made less and less, until within three weeks none was taken. In the tapering off process a glass of cold water was taken on each alternate morning, the magnesia being taken on the other. An orange was then taken for some time each morning before breakfast, after medicine was stopped. The patient was gaining in flesh; complexion was improving, and, much to the delight of all, especially of the lady herself, the acne was now gone. The patient has been under constant observation ever since and no return of the old troubles has ever occurred.

This case is a fair specimen of many that can be pro-

duced from my notes of cases. Originality is not claimed for this mode of treatment, and yet the literature on habitual constipation, so far as I know, does not anywhere combine all these elements of treatment. The points of treatment seem all important in the matter of regularity, solicitation, and non-purgation, and it is believed that these matters, faithfully carried out, together with proper diet and the mildest possible laxatives, will be efficacious very quickly in many, if not all, cases where there is no actual paralysis of the bowels.

Progress of Medical Science.

Neurasthenia.—The *Post-Graduate* for January, 1891, contains Dr. Charles L. Dana's recent paper on neurasthenia, which is defined as a morbid condition of the nervous system, presenting excessive irritability and weakness as underlying characteristics. The modifying elements are age, sex, and the neuropathic constitution. Neurasthenics suffer from a peculiar feeling of nervousness, discomfort, unrest, or a sense of tension. Interest in work is lost, there is dread of responsibility, and various morbid fears. Some idea fixes itself upon the mind, and the patient cannot rid himself of it. Sleep is poor, and the neurasthenic awakes unrefreshed. There is difficulty in fixing the mind upon work. About half the cases suffer from headache—diffuse, frontal, or occipital. There is always some weakness and irritability of eyesight. The visual field is normal, but sensation in its periphery tires easily, so that after long testing there is apparently a concentric limitation of the field. The color sense is unaffected. Muscular insufficiencies often occur. Visual memories are lessened. Faces and places are not well remembered. Neurasthenics bear visual irritation badly. Hypermetropia or astigmatism may keep up neurasthenia, but will not in themselves cause it. Attention to the eyes alone, as a means of cure, is irrational and disappointing.

Noise creates great distress. This is usually due to the general mental irritability. Sometimes there is distinct hyperacousia, and slight noises or agreeable music drive the patient nearly wild. Alterations in taste occur with digestive complications. There is a general oversensitiveness to odors. General muscular strength is lessened, the patient tiring, or even collapsing, after slight exertion. There may be fine tremor of the hands after muscular or mental effort. Palpitation of the heart occurs easily. The pulse has frequent and rapid variations in tension. In both sexes there are genital irregularities. The digestive organs, including the metabolic tissues of the liver, are almost always at fault. Gastric symptoms of neurasthenia are those resulting from the action of ordinary or somewhat impaired digestive processes upon over-irritable gastric nerves, or upon a generally over-irritable and weak nervous system. A neurasthenic liver is one of the most common and fundamental conditions of the neurasthenic state. This produces intestinal dyspepsia, fermentation, and constipation. The blood absorbs an excess of ptomaïnes and imperfectly oxidized products. Hence paræsthesia, somnolence, and head pressure. The urine in the young and neuropathic cases is variable in specific gravity, generally low. Phosphates, earthy and alkaline, are excreted in excess. Nitrogeneous solids are often inadequate in amount. Oxalates are found in older cases, but indicate no more than does excess of urates—*i.e.*, a lithæmic state. The amount of urine passed is variable. Sometimes there is polyuria, but, on the whole, the total amount is variable. Respirations are normal in number, but shallow, and deficient respiratory expansion may be noted. Younger patients and women are generally anæmic, but middle-aged adults are not, the face being full and ruddy, and the mucous membrane of good color.

When neurasthenia begins before the age of twenty-five, there is more distinct evidence of neuropathic constitution and inheritance. Mental symptoms are more marked, approaching those of hypochondriasis, and there is greater depression and greater introspection. Neurasthenia of the climacteric, in both men and women, is of comparatively short duration and favorable in its course. Neurasthenia in women shows itself by a greater dominance of sensory and irritative symptoms. There is more pain, headache, neuralgia, and spinal ache, and a greater subjective sensation of "nervousness," more restlessness and irritability. There is greater variability in the rise and fall of symptoms. The neurasthenic woman under excitement does all that a healthy woman can, then collapses entirely. Women of strong purpose will be thus alternately sick and helpless, or bright, active, and cheerful. Those of weak will, aided by the mistaken ministrations of sympathetic friends, get in bed and stay there, drifting into permanent invalidism, because overcome by the pain and weariness that active movement excites. Hysteria often complicates these cases. "Crises" of palpitation occur, of vomiting, tympanites, diarrhœa, pulmonary oppression, syncope, and emotional excitement. Nutrition suffers more than in men, the disorder is of a severer form, and the patient emaciates. Symptoms are slightly exaggerated at the time of menstruation. Rarely, if ever, beginning before eighteen or after fifty, neurasthenia occurs in the following order as regards age: First, between eighteen and thirty; then, between thirty and forty; and less frequently between forty and fifty. Exciting causes are excessive mental strain, sudden shocks, injuries, frights, sunstroke, excessive child-bearing, domestic troubles, sexual excesses, especially masturbation, irregularities and excess in eating, drinking, and smoking. Overwork does not cause it, provided there is no great mental worry. Even these can be borne if the patient is regular in eating and sleeping, and does not drink or smoke too much. Reckless indulgence in athletics during youth, particularly if combined with the overuse of tobacco, may be a cause. In some cases it follows apparently some single powerful physical exertion. Malarial poisoning, syphilis, the infective fevers, particularly cerebro-spinal meningitis, are important agents in causing neurasthenia. Of reflex influences that cause and keep it up, disturbances of the stomach, intestines, and liver are by all odds the most important; next come irritations from the pelvic and generative organs.

Neurasthenia is a condition in which the nutrition of the nerve-cells is primarily at fault. These cells have lost their power of building themselves up into stabler compounds. They break down under slight irritation, and consequently send out but feeble impulses. It is thought by some that this dystrophic condition especially involves those parts which make up the vaso-motor neuro-mechanism. If this be so, it is the nervous tissue of the medulla and central parts of the spinal gray matter that are most involved. There is little doubt, however, that the cortical gray matter and higher centres of the brain are also implicated, for mental symptoms are always prominent. Peripheral nerves are not primarily at fault. Cerebral and spinal hyperæmiæ are secondary to nervous disturbance. Neurasthenia is primarily cellular and secondarily vascular.

The duration of the disease is from one to ten years, depending largely upon treatment and habits of life. Most patients get well, or practically well, with some reminders that they cannot overtax themselves or do the work of those of strong nerves. The late years are the best, owing to lessened nervous sensibility and early, orderly, and temperate living. Neurasthenics, if they get well, get old. With care, neurasthenia may readily be differentiated from simple nervousness, degenerative forms of insanity, such as *folie du doute*, from hypochondriasis, from melancholia, hysteria, and spinal irritation. The patient should have his course of treatment laid out for him. Rest, or lessening of business or domestic duties is fundamental. While travelling is bad, a sojourn

at such places as the Azores, West Indies, Bermuda, or some special point in Southern Europe where out-door life is possible, is of benefit. Diet should be rather nitrogeneous than otherwise. Fats, green vegetables, and fruits may be added. Sugars and starches are to be avoided, though malt preparations usually agree. Nutrition must be carefully watched, the patient must be weighed and sometimes fattened, using water, malt, oil, and cream for this purpose. In many cases a low diet, but one perfectly digestible, is indicated. Cold sponge-baths, the shower, a strong jet of cold water on the back, a cold plunge, or the wet pack, are measures almost invariably indicated. Lukewarm baths, 95° F. to 98° F., for half an hour at night, relieve the paræsthesiæ and insomnia. The skin should have a thorough rubbing every day. Interesting respiratory exercises that expand the lungs should be encouraged. Drugs that are most useful are the bromides, nux vomica, mineral acids, quinine, valerian, the hypnotics, and saline and alkaline laxatives. Bromide of sodium or potassium should be given, in doses of fifteen or twenty grains, three times daily, for only a week, and then gradually reduced to one-half dose, once daily; quinine should be given carefully, as it may increase the nervousness. In neurasthenic women with painful backs or hysterical complications too much cannot be said for electricity, which should be given three or four times weekly and then suspended. General and spinal galvanization and the static sparks are the especially efficient forms.

Emphysema Following Rupture of the Eustachian Tube.—At a recent meeting of the Medical Society of Victoria (*The Australian Medical Journal*) Dr. Kenny related a case of this rare accident. The patient had been under treatment for deafness: On July 31, 1890, a catgut bougie was passed into the left tube as usual. At the end of consultation, patient made attempts to inflate his tubes, according to Valsalva's method, using a great amount of force, and causing marked congestion of the head. About eight hours later he was called to see him. He found him semi-collapsed, with a grave sense of impending danger, dyspnœa, intense constricting girdle-pain in the chest, about the level of the nipples, and a tendency to syncope. He and his wife told the doctor that shortly after leaving his surgery a swelling suddenly appeared in the left side of the neck, below the ear, and behind the ramus of the lower jaw. This had increased both upward and downward, and his present symptoms had come on gradually—had been more severe, but were now abating. While examining, patient had an attack of syncope, which yielded to inhalation of nitrite of amyl (three-minim capsule). Marked crepitation on palpation was observed, extending from some distance above the left ear down along the front edge of the sterno-mastoid, underneath the lower jaw and the floor of the mouth, reaching as high as the right ear, extending across the front of the neck to the right sterno-mastoid, thence to the sternum, being there lost in the chest. It was thought some crepitation could be felt below the ensiform cartilage, but this was doubtful. There was, clearly, extensive emphysema of the subcutaneous cellular tissue, originating in the neighborhood of the left Eustachian tube, and extending into the mediastinum, mechanically interfering with respiration and the heart's action. On examination, no laceration or rupture in the nose or naso-pharynx could be detected, the point of entry of the air was evidently in the Eustachian tube, through a tear caused by the bougie, and enlarged by the patient's efforts, or possibly caused by those efforts. The patient was relieved by taking cardiac and respiratory stimulants, hot fomentations to the neck, boroglyceride as a gargle and nasal douche. The emphysema gradually disappeared, though slight crepitation could be felt for some three or four days under the chin. These cases are interesting because of their rarity. Hartmann, of Berlin, in his book on the ear, states that "alarming and even dangerous accidents may be caused by the catheter injuring the mucous membrane, and inflating the subjacent and surrounding tissues with air. This happens most frequently after passing bougies into the Eustachian tube."

Hints on Disinfection.—Dr. von Esmarch has enumerated some of the points that should be specially attended to in the use of disinfecting apparatus. He agrees with most authorities that steam, either circulating or under pressure, and without the admixture of air, is by far the best means of disinfecting clothing and other articles that will withstand the action of moist heat. As to whether circulating steam or steam under pressure is best, he thinks that it is entirely a matter of convenience, but it will be readily understood that where large chambers have to be constructed it would be difficult and extremely expensive to build them of sufficient strength to withstand any great pressure from within. Even in the case of smaller sterilizing chambers, the expense of obtaining them sufficiently strong is so great that in most cases their use is precluded. The main desiderata for a perfect disinfecting apparatus are that it shall be close to the source of the steam-supply; that there shall be sufficient steam developed to fill it thoroughly, and to keep up the temperature for some length of time; that the steam shall be sent in at the top and passed out at the bottom, in order that every crevice of the apparatus may be filled; and that where it is used in large establishments, it shall be placed between two rooms, into one of which articles to be treated are to be taken, and passed in at one door of the sterilizer; while the other room should be at the other end of the sterilizer, and into it the clothes should be passed, so that they shall not again be brought into contact with unsterilized clothing, etc. Articles that are to be disinfected should not be allowed to remain too long in contact with steam, and before being steamed they should be thoroughly heated, so that there is no opportunity for the steam to condense on cold surfaces, and in the same way they should be well dried by heat after the steaming process has been concluded. Twenty minutes is quite long enough to allow most ordinary articles to remain exposed to a moist heat of 212° F., so that they should be left for this length of time after the temperature has once been raised to this point, this being determined by an electrical contact thermometer, or a thermometer placed in a tube through which the steam escapes; some simple manometer should be used to determine the pressure that has been obtained by super-heating the steam. The greatest attention should be paid to this point of time of exposure, for it is the experience of all medical officers of health that nothing deters people from sending their clothes to be sterilized so much as the fact that they are frequently ruined by too long an exposure to the action of the steam. Discrimination must also be used in determining what articles can be safely steamed, and an officer of health who ordered stamped plush, leather, skins, or waterproof material to be exposed to heat would render himself liable to be heartily laughed at by all practical men. Grease should always be removed if possible before the articles are put into the sterilizer, otherwise it becomes fluid and is liable to spread to other parts.—*Hygienische Rundschau.*

The Blood in Pneumonia.—Dr. Kikodze has published some observations on the blood during pneumonia. He found that during the course of this disease the white corpuscles increase in number to as much as double, or even treble, what they are in healthy persons. The increase is observed in the fully mature and over-mature corpuscles rather than in the young ones. It is worthy of note that in fatal and very severe cases no increase in the white corpuscles is found. As a rule, however, the increase begins even before the physical signs of pneumonia are detected. It persists from that time onward without any great variations, to the crisis, immediately after which it suddenly falls. It appears to be due to the re-entry into the circulation of the corpuscles which have passed out

into the alveolar spaces; hence, probably, the preponderance of over-mature corpuscles. After the crisis this preponderance ceases.

Salol as an Antiseptic in Cancer of the Uterus.—Of the symptoms characterizing cancer of the uterus in its later stages, more especially when it is complicated by a vesico-vaginal fistula, none is more trying to the poor sufferer than the repulsive odor proceeding from the diseased surface. The palliative means in ordinary use, such as injections of carbolic lotion, sublimate and iodized solutions, vaginal suppositories of iodoform, etc., are only partially successful in mitigating the fetor which renders the last days of the patient a veritable martyrdom to herself and to her *entourage*. In salol administered internally in daily doses of from two to four grammes (increased if need be to six or eight grammes, and continued uninterruptedly for a long time) Dr. Marty claims to have discovered a sovereign remedy for this state of things, provided there be a communication between the vagina and the bladder. The urine, flowing constantly over the diseased tissues and impregnated with the products of the decomposition of the salol—viz., a phenylsulphate and salicylic acid—keeps the parts sweet, and its action adds greatly to the comfort of the patient.

Periodic Paralysis.—Dr. Goldflam describes a peculiar form of paralysis which is periodic, hereditary, and, according to him, autotoxic The case which he describes occurred in a boy, aged seventeen, who, three years previously, had been attacked in the night with a sudden paralysis affecting the extremities and trunk. This lasted three days and since then had frequently recurred, more especially in the spring of the year. The attacks generally commenced in the evening. The first symptom noticed was an almost unbearable itching over the site of the paralysis; there was always constipation. The paralysis was not absolute, the knee reflex was lessened, the plantar reflex lost; sensibility was not affected. There was no tenderness over the muscles or nerves, and no bladder symptoms. The backward and forward movements of the head were deficient. The muscles of the face, tongue, eye, and œsophagus were not attacked; speech and movements of respiration were normal. The faradic irritability of the large nerve-trunks in the upper extremities was greatly diminished during the attacks, and slightly so in the lower extremities. There was complete absence of direct muscular irritability. Reaction to the galvanic current was also considerably weakened. The attack lasted forty-eight hours, and concluded with profuse perspiration. The peroneal muscles alone remained affected for some time. After the attack all the nerves and muscles responded promptly to both currents. There was at no time a rise of temperature. Examination of the blood and urine gave negative results. One of the most interesting facts in connection with this case is that eleven other members of the patient's family were subject to similar attacks, but only on the mother's side; the father's family was completely free. The hereditary character of this disease followed no regular course; occasionally all the females were attacked, leaving out the males, and sometimes the reverse was the case. The frequency of the attacks in the different sufferers also varied considerably, but they did not seem to affect the ordinary duration of life. Dr. Goldflam has collected several such cases from medical literature, and the following is a summary of his investigations: In the intervals between the attacks there was some diminution in the electrical reaction in the smaller muscles of the hand, together with the reaction of degeneration. Although improvement occurred in most of the cases, this was interrupted by relapses. As regards the pathology of the disease, Dr. Goldflam believes that the muscles themselves are affected, or, perhaps, the nerve endings, such as occurs in poisoning by cocaine.—*Wiener Medicinische Presse.*

The Etiology of Tinnitus.—We are now able in almost every instance to determine the cause of any form of noise in the head and ears, and by the aid of instruments refer them to the part of the head or ear to which they belong. Again, we can reduce the noises to three classes, and as soon as the patient gives the history of the form he suffers from we can classify it as: 1. The constant rushing and knocking or pulsating noises. These are the most rare, and almost always depend upon hyperæmia, venous or arterial effusion of blood, serum, or pus in labyrinth, semicircular canals, ecchymosis in the vestibule, hyperæmia of the cochlea; extra-aural, as aneurism, anæmia, chlorosis, lithæmia, temporary or permanent changes in blood-vessels in and around the ear. 2. Moist sounds of great variety, depending on the patient's occupation and intelligence, but chiefly called gurgling, bubbling, boiling, singing, whistling, shell-like roaring, etc. These indicate the presence of fluid on the drum or in the cavity, catarrh of the Eustachian canal, auditory canal, mastoid cells, or post-nasal and pharyngeal spaces. 3. Dry roaring and ringing sounds, comprising a large number of diseases of the auditory nerve, direct or reflex. Among the direct, chronic non-suppurative middle-ear catarrh, affections of the muscular and nervous supply of the ear, cerebro-spinal-meningitis, pressure of tumors in or about the ear or auditory nerve, Ménière's and syphilitic disease of the nervous apparatus of the ear. Certain habits induce the noises. Use of stimulants and tobacco, a full meal, great bodily or mental fatigue, mental action with artificial light and heat near the head. Certain vocations increase the noises, as telegraph operatives, locomotive engineers, boiler-makers, machine workers in cotton or wool factories. Mental influences: A happy frame of mind, pleasant active occupation, and riding in carriage or train, during the daytime diminish these sounds. Ill-temper, extremes of temperature, indigestion, the night with its quiet, meeting strangers, etc., increase the sounds. In women tinnitus is apt to appear with sick stomach during pregnancy and menstruation. Painful noises attend diseased kidneys, especially diabetes and Bright's. Subjective sounds in middle-ear disease can be changed by pressure with the finger on the mastoid or first cervical vertebra, and increased by closing the external meatus. In post-mortems on persons who have suffered tinnitus for long periods without any apparent disease of the ear, there has been found disease of the semicircular canals, ecchymosis of the vestibule, hyperæmia of the cochlea, and general enlargement and fulness of the vessels of the labyrinth.—*Medical Analectic.*

Pathology and Treatment of Muscular Torticollis.—The *Mercredi Médical* for March 4, 1891, contains the report of a meeting of the Vienna Practitioners' Society, in which this subject was considered and discussed. According to Dr. Lorenz, the too frequent imperfect results obtained were due either to insufficient division of the contracted muscle or to defective post-surgical treatment. Muscular torticollis, it is needless to mention, is caused by a contraction in one sterno-cleido mastoid muscle. The head inclines to the opposite side, usually backward, sometimes forward, and displaced laterally from the median line. A distinction must be made between mild and severe cases. In its severe form there is great deformity of the cervical vertebræ, scoliosis with convexity toward the affected side, and lateral displacement toward the same side. In mild cases the scoliosis presents a convexity toward the unaffected side; and toward this same side there is lateral displacement of the head. In both instances there is compensatory scoliosis in the dorsal region of the vertebral column. Mild cases are much more rebellious to treatment than severe ones, in the back of the neck, on a level with scoliotic convexity, there is usually a strongly-defined pad of muscle, formed by the muscles of the nucha. On the opposite side there is a depression. In severe cases, division of the sterno-cleido mastoid muscle permits at once the normal erect position

of the head. Not so in torticollis of slight degree. Here the deformity of the cervical vertebral column prevents a perfect result. An open incision is best, though subcutaneous cutting presents disadvantages from the æsthetic point of view. It is often the fear of scars that prevents a completely successful operation. To make an incision of which the scar can later be concealed with ease, cut in between the two heads of the muscle. By opening wide the lips of the wound the contracted muscle can readily be severed. Healing should be by first intention and the stitches removed in a week. Post-surgical treatment is even a greater factor in cure than surgical interference. The head should receive passive movements, and be moved voluntarily in certain directions. Later, general massage of the head is in order. Appliances are of comparatively little service, for they cannot overcome the influence of the spinal deformity. Results obtained from open incision Dr. Billroth considered sufficiently satisfactory, in spite of the presence of deformity in the region of the cervical vertebræ. One of his patients operated upon died of septicæmia. The æsthetic fault of the operation consists in the impossibility of doing away with the furrow left in front of the muscle's anterior border. Dr. Lorenz believed that the rapid reunion of the severed ends of the muscle, by causing strong tension, would fill out the depression. While Dr. Weinlecher preferred the subcutaneous operation, he agreed with the others in acknowledging the importance of after-treatment. One valuable suggestion was made by Dr. Weinlecher, to wit: In the subcutaneous method of operating for torticollis, turn the head in a way to induce considerable tension of the muscle, thus facilitating its complete division. Were the subcutaneous method as defective as it is sometimes considered there would be frequent relapses, which is not the case so far.

Laryngeal Chorea. — The *Gazette Hebdomadaire de Médecine et de Chirurgie*, March 14, 1891, quoting from a Spanish journal, cites a case of dysphonia with dry cough as a sequel of grippe in a twenty-year-old patient without hysterical stigmata or previous neuropathic history. The cough, obstinate and painful, was quieter at night. The laryngoscope revealed alternate contraction and relaxation of the vocal cords. Upon this condition the author, Dr. Furundarena Labat, bases the diagnosis of laryngeal chorea. There was also hypertrophy of the nasal mucous membrane. Cocaine applied to this membrane stopped the laryngeal spasm, while irritation of the membrane would increase it. Removal of the thickened tissues effected a complete cure of the laryngeal disturbance.

Cocaine in Dental Surgery.—Dr. A. Préterre, a dentist of Paris, has studied carefully the action of cocaine in preventing pain in dental surgery, and has come to the conclusion that it is an unreliable anæsthetic in such cases, and that its employment is by no means free from danger. More accidents happened in one hundred cases in which cocaine was used than in thirty thousand in which anæsthesia was obtained by the use of nitrous oxide gas, and the writerfo therere recommends that the latter be always used in preference to cocaine.

The Creed of an Experienced Gynecologist. — Professor Goodell says that he has learned to unlearn a great deal in the treatment of diseases of women, and as a result of this he has adopted a short but comprehensive gynecological creed, which runs as follows: "I believe that the physician who recognizes the complexity of woman's nervous organization and appreciates its tyranny, will touch her well-being at more points and with a keener perception of its wants than the one who holds the opinion that woman is woman because she has a womb." —*College and Clinical Record.*

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, April 20, 1891.

SAMUEL B. W. MCLEOD, M.D., PRESIDENT, IN THE CHAIR.

Case of Traumatic Occlusion of the External Auditory Meatus.—DR. MATTHIAS L. FOSTER presented a boy, aged eleven, who was injured last July by a heavy box falling upon him. He was admitted to the New York Hospital shortly afterward, where they dressed a wound involving the cheek and lobe of the ear on the right side. He was soon able to be out. In October he appeared at the Manhattan Eye and Ear Hospital on account of occlusion of the right ear, and was treated by Dr. Pomeroy by progressive dilatation of the small canal leading into the ear. Rubber tubes were employed, increasing in size, keeping up constant pressure against the hypertrophic growth. The watch could be heard only on contact before dilatation; afterward the hearing had become about normal. There was, however, a tendency for reocclusion to take place, and the results of treatment after such accidents were for this reason unsatisfactory. He said that such cases existed sometimes from birth. But he had been able to find accounts of only two which were clearly of traumatic origin. He suggested that multiple incisions might be practised in such a way as to keep the auditory canal patent.

A Case Cured by Galvanism.—DR. OPPENHEIMER said he had seen two cases like the one narrated by Dr. Foster, in one he succeeded in keeping the canal open by a sort of primitive electric battery, connecting a conical silver speculum introduced into the canal by a fine copper wire with a small tin plate applied behind the ear, the latter only requiring to be dampened (using vinegar), the discharges from the canal keeping the former moist. The granulations were thus repressed, and the surface healed in about six weeks, giving a perfectly satisfactory result. He had never published the case.

The Phonograph and Micro-Graphophone in Medical and Other Sciences.—DR. J. MOUNT BLEYER read the paper and demonstrated the subject by means of two phonographs and one micro-graphophone. He referred to the invention of the phonograph ten years ago by Mr. Edison, his prediction regarding its uses, the fact that, for want of perfection in the mechanism it had remained a toy until a few months ago, that now it was capable of recording and reproducing any kind of sound. Without going into the details of the construction of the machine, he said the principle of its action consisted in recording on a revolving cylinder of wax the sound wave impressions of a delicate diaphragm through the intervention of a needle. Reversing the process, the diaphragm was made to undergo the same wave like motions and reproduce the sounds by turning the cylinder and allowing the needle connected with the diaphragm to retrace its steps. If the cylinder were turned slower than when the impres sions were recorded the voice would be reproduced as spoken, but in a lower tone; if turned faster it would be reproduced at a higher pitch. It was a somewhat curious fact, however, that the timbre remained the same. He said the company's men would keep the instrument in order, but it was better for one to master its mechanism and be able to repair anything which might happen to get out of working order.

DR. BLEYER said he had been working some years in applying the phonograph to medical science. The instrument could be made to record many sounds connected with the respiratory tract in both the normal and abnormal state. The voice sounds could be recorded and kept for comparison in health and disease. A record of sounds produced in whooping-cough, asthma, croup, diphtheria, would be of great value. In the two latter diseases one

would obtain from it a clue as to when to operate for dyspnœa. It was also of interest to have a record of the cry of maniacs, hysterics, etc.

In other directions the instrument was of value in learning to pronounce correctly foreign languages, in correcting errors in vocalization on the part of actors, in the preservation of the speech of distinguished persons, in the study of natural history, in setting type by sound, etc. The phonograph required the use of hearing tubes.

The principle of construction and action of the micro-graphophone, invented by Lieutenant G. Bettini, whom he introduced, was similar in many respects to that of the phonograph, but was intended to be an improvement on the latter in reproducing sound with greater intensity. He said this was the first time the inventor had demonstrated his instrument in public, and then only after much personal persuasion on the part of the author. The chief feature distinguishing the micro-graphophone from the phonograph was in the construction of the vibrating diaphragm. This was larger, was divided into several parts, and the recording needle was connected with it at more than one point by a "spider." In this way dead points were obviated, or, rather, the recording point being connected with different parts of the diaphragm, one part becoming dead, another part would transmit the wave to the needle and through it make the impression upon the wax.

Mr. Bettini then sang, spoke, coughed, and whistled into his instrument, the instrument reproducing the sounds with great accuracy and distinctness. He further explained the construction of his machine, and said that if the needle were attached to the diaphragm at only one point, that point might happen to be a dead one, although other portions of the membrane were vibrating, and thus fail to record some of the sounds. To obviate this, he had divided the diaphragm into different parts, and made connection with the needle by means of the spider.

Cylinders were passed through the phonograph, reproducing the sounds of singing, coughing, hoarseness, sneezing, crying of a baby, etc. Dr. Bleyer said he was experimenting, trying to record the heart sounds with sufficient intensity to be of medical value.

Correspondence.

"NOTHING NEW UNDER THE SUN."

To the Editor of the Medical Record.

Sir: The article by a member of the profession in Indiana which appeared in the Medical Record of the 4th inst., on the treatment of diphtheria with "sulphate of zinc" carries me back to the time when I was a student, and strengthens my faith in the principles of therapeutics taught me many years ago.

During the years 1874–75, while I was under the tutelage of a distinguished physician, who was a student of the illustrious B. W. Dudley, of Kentucky, an epidemic of diphtheria was prevailing in eastern North Carolina. My preceptor, whose practice extended over a territory of four counties, was so successful in the management of this formidable and destructive malady that his treatment was the subject of much favorable comment on the part of the laity. One day, as he was passing through the office, I said to him: "Doctor, how do you treat diphtheria?" "With the sulphate of zinc," he replied. In his absence, as a dernier ressort, I was sometimes asked to prescribe for the little sufferers, and would use the same drug with like results. Since that time I have been using sulphate of zinc in diphtheria and other malignant throat affections with good results. I heartily endorse every word the gentleman from Indiana has said, and am glad that he has called the attention of the profession to so important a point in the treatment of a malady which has spread its ravages all over this fair land of ours and brought sorrow and sadness to our many otherwise happy homes.

R. C. Ellis, M.D.

Waynesville, N. C., April 13, 1891.

MEDICAL MEN AND TEMPERANCE.

To the Editor of the Medical Record.

Sir: Thanks for the candid and courteous response in your issue of the 14th inst. Even if your space and time permitted I would have no desire to prolong the discussion, but with your kind approval, I would ask the following questions. It is said, "People are better without alcohol, but there is a contingent of grown-up persons who can drink it temperately without harm. This is what physiology teaches and medical experience confirms."

Now, is it not true that experience also teaches that the man who most fully persuades himself that he is one of this fortunate "contingent," is usually the one who should most carefully guard against the use of alcohol as a beverage? "*Humanum est errare.*" Second; In view of the sad fact, taught by statistics, that about one person out of every fifty becomes a drunkard, and of the positive harm thus resulting to the victim and to society, is it not the duty of every "philosophic physician" to forego the negative benefit to be derived from the "temperate" use of alcohol as a beverage, for the sake of his weaker brother whom it causes to offend? Example is ever more powerful than precept, and youth is ever prone to imitate the ways of "grown-up persons."

Emerson says "The Mohammedans conquered Europe on barley"—meaning, evidently, that this portable food sufficed for the simple wants of both themselves and of their incomparable steeds. Had the Europeans resorted more to barley and less to "John Barleycorn," is it likely that they would have needed eight hundred years in which to entirely expel the invaders—those water-drinking Christian and alcohol-hating invaders, who brought to benighted Europe science and art, and all polite learning; who founded medical hospitals and schools, and noble cities, the remains of which even now are the admiration of the world.

Respectfully,

Old Subscriber.

SCARLET FEVER AND THE IMMUNITY OF THE JAPANESE.

To the Editor of the Medical Record.

Sir: Your readers will perhaps remember my article in the Record of March 21st (it consisted in a letter to Professor Law, about scarlet fever in its relation to Japan). I tried to establish the fact that the latter country enjoys a total, or, at least, an almost total immunity from that disease. Even Baelz, who claims to have seen several mild cases of the disease as it exemplifies itself in European countries, admits that he never saw it in Japanese women or children. I have recently received a letter from Surgeon Suzuki of the Japanese Navy on the subject. He declares that he never saw a case of scarlet fever in Japan, during his whole practice; he is a graduate of the University of Tokio, which means that he attended the clinics of the Tokio hospitals during at least six years.

I had previously mentioned, in the Record of January 10th, an attempt I had made to inoculate a Japanese with scarlet fever. I thought that it might be possible to transfer the immunity from one race to the other, either through a resulting modified disease or by pure blood inoculation. I referred to this experiment in a letter to Professor Alexander Edington, of Edinburgh, mentioning at the same time the report of a Japanese case of scarlet fever at Cornell University, published in the Medical Record of February 21st, by Dr. Kirkendall. Of course, if there is no mistake in Dr. Kirkendall's diagnosis, the case would show, as Professor Law suggested to me, susceptibility acquired by acclimation. From Professor

Edington's answer I extract the following points, which I am authorized to make use of.

1. "I am not aware of any known cases of scarlet fever occurring among Japanese."

2. "Your attempted inoculation may be fallacious; scarlet desquamation is not at all times virulent, but is most so about the 25th to the 30th day (roughly speaking)."

3. "Klein and Powers's attempts were not quite clearly successful either postively or negatively."

4. "Inasmuch as certain pathogenic species can in an open wound, in an immune animal, produce a pyogenic or perhaps a saprogenic rather than a truly pathogenic manifestation, it is clear that in an immune human race a disease obtaining with certain well-defined symptoms in the susceptible races may if it gains a footing at all manifest its presence under quite another guise. The analogy is complete in the higher vegetable forms, and why should we not admit it here? The evolution of disease is a most interesting question, and I am sorry to find that medical science attempts to be too dogmatic and narrow-minded when such general questions are to be discussed."

Professor Edington has just been appointed Bacteriologist to the government at Cape-town. When he arrives there he will again look into this most interesting matter and let me know whatever conclusions he may reach.

Very Respectfully,

ALBERT L. ASHMEAD.

A HOOK FOR THE REMOVAL OF FOREIGN BODIES FROM THE EAR.[1]

BY E. MEIERHOF, M.D.,

SURGEON FOR EYE AND EAR DISEASES IN THE OUT-DOOR DEPARTMENT MT. SINAI HOSPITAL, ETC.

FOR those cases of impaction of foreign bodies in the external auditory canal which are not removable by irrigation, particularly bodies, such as beans, which swell from the absorption of water, I have devised a hook for their removal which has proven very efficient in my hands. The instrument, made for me by Messrs. John Reynders & Co., consists simply of a shank in a handle with a bend at the end of the shank at right angles, the little bend which forms the hook is slightly curved laterally. The object of this lateral curve is intended that the point of the hook shall not come in contact with the superior wall of the canal.

For the removal of a foreign body pass the hook into the canal, keeping the point upward, with the convex side of the hook lightly against the posterior wall of the canal until it passes in between the foreign body and the posterior wall, after which rotate the handle on its axis so that the point of the hook will bury itself somewhat into the foreign body, gentle traction will then dislodge the offending object.

57 EAST SIXTY-FOURTH STREET.

To Reward Koch.—A certain Colonel Nolan has addressed a question in the British Parliament to the First Lord of the Treasury respecting the intention of the Government to confer a suitable pecuniary reward on Dr. Koch for his "eminent services to humanity." The reply was that Koch's great reward must be the appreciation of the value of his discovery by the medical profession in all parts of the world. Perhaps this is better than any "pecuniary reward."

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 19, 1891, to April 25, 1891.

KNEEDLER, WILLIAM L., Captain and Assistant Surgeon. By direction of the Acting Secretary of War, is relieved from duty at Jackson Barracks, La., and will report in person to the commanding officer at Fort Logan, Col., for duty at that post; reporting also by letter to the Commanding General, Department of the Missouri S. O. 88, par. 2. Headquarters of the Army, A. G. O., Washington, D. C., April 18, 1891.

BUSHNELL, GEORGE E., Captain and Assistant Surgeon, Camp Pilot Butte, Wyo. Granted leave of absence for twenty-one days, to take effect on or about May 1st next. S. O. 49, par. 9, Department of the Platte, Omaha, Neb., April 20, 1891.

WOODHULL, ALFRED A., Major and Surgeon. By direction of the Acting Secretary of War, is detailed to represent the Medical Department of the Army at the International Congress of Hygiene and Demography at its meeting in London, England, from August 10 to 17, 1891. He will leave his present station not later than June 1, 1891, and will proceed to London. After the adjournment of the Congress he will return to his proper station. While abroad under this order, and before returning to the United States, he will visit on official business such points in Great Britain as may be deemed necessary by the Surgeon-General of the Army. S. O. 91, par. 17, A. G. O., Washington, D. C., April 22, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 25, 1891.

MCMURTRIE, D., Medical Inspector. Detached from Navy Yard, New York, and ordered to the Lancaster.

KERSHNER, EDWARD, Medical Inspector. Detached from Marine Rendezvous, and ordered to Navy Yard, New York.

HERNDON, C. G., Surgeon. Detached from Naval Hospital, New York, and ordered to the Marine Rendezvous.

GARDNER, JAMES E., Passed Assistant Surgeon. Ordered to Naval Hospital, New York.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 25, 1891.

	Cases.	Deaths.
Typhus fever	1	0
Typhoid fever	14	4
Scarlet fever	181	49
Cerebro-spinal meningitis	8	10
Measles	396	20
Diphtheria	82	28
Small-pox	1	1
Varicella	12	0
Pertussis	0	fi8
Erysipelas	2	0
Mumps	0	0
Rötheln	0	0

Chinese Gynecology.—A patient with prolapsed uterus lately consulted a Chinese doctor, when the learned man ordered a blister to the shaved crown of her head, in order to draw the prolapsed organ back again. During the treatment the patient's attention was directed entirely to her head.

A NEW METHOD FOR DIRECT ELECTRIZATION OF THE STOMACH.[1]

BY MAX EINHORN, M.D.,

PHYSICIAN TO THE GERMAN DISPENSARY, AND INSTRUCTOR IN CLINICAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

MR. PRESIDENT AND GENTLEMEN: Numerous experiments have been made in the study of the influence of electricity upon the stomach and intestines; all of them serve to demonstrate the physiological effects of this agent.

Ludwig and Weber,[2] von Ziemssen [3] and Bocci [4] have stated that on animals the faradic, as well as the galvanic, current, applied directly to the stomach, causes contractions of this organ, and produces secretion of the gastric juice.

Schillbach,[5] upon applying the galvanic current to the bowels of a rabbit, observed intense contractions at the site of the anode, followed by peristaltic movements. Fubini [6] lately demonstrated, after making a Vella's double intestinal fistula, that electricity quickens intestinal peristalsis to a high degree, viz., about five or six times.

The influence of electricity upon the stomach and intestines thus being evident, it is perfectly right to endeavor to make use of this means in the therapeutics of these organs.

For many years past, numerous authors have employed electricity in affections of the stomach and intestines. The method generally used for this purpose consisted in the percutaneous application of the current; usually one electrode was held in the neighborhood of the vertebral column at about the sixth dorsal vertebra on the left side, the second electrode being placed at the epigastrium.

A. D. Rockwell and M. Beard [7] were among the first to make use of electricity on a large scale in the treatment of nervous dyspepsias. To the application of electricity to the stomach they added general electrization, and had the most brilliant results.

Neftel,[8] in 1876, says: "For more than eight years I used the induced current in the treatment of dilatations of the stomach arising from chronic catarrh, with much success."

Fuerstner [9] has treated three cases of suddenly appearing attacks of gastric tympanites in nervous females with the galvanic current, and could always observe an amelioration of the complaints. Each time after the galvanization Fuerstner found the limits of the stomach diminished. Based upon this fact he recommends the same method of treatment in atonic dilatations of the stomach.

Oka and Harada [10] treated thirteen stomach patients with the faradic current, with the result that five were cured, six improved, and two uninfluenced. Leube,[11] in the treatment of nervous dyspepsia recommends the daily application of electricity. Lente [2] and Semmola [3] have obtained splendid results by the use of electricity in cases of vomiting of the most various nature. Lente recommends electricity as a cure for sea sickness, though he has not given the matter a sufficient trial. Richter [4] advises the use of electricity in nervous dyspepsia and nervous enteropathy. Leubuscher [5] speaks highly of the application of the galvanic current in pathological conditions of the lower intestines.

Besides these clinical facts, there have lately been added some more exact notes as regards the physiological effects of percutaneous electricity of the stomach in man. Ewald and myself [6] have been able to demonstrate an acceleration of the motor faculty of the stomach under the influence of percutaneous faradization, by the appearance of the salol-test in the urine about one-fourth of an hour earlier than otherwise. A. Hoffmann [7] showed that the galvanic current percutaneously applied in the gastric region for twenty minutes produces an abundant secretion of gastric juice.

Although the favorable influence of electricity, even percutaneously applied, is quite evident in numerous affections of the stomach and intestines, it, however, remains questionable whether any of the produced electricity penetrates to the stomach. The main currents undoubtedly go through the skin and muscles, and if any of them reach the stomach, they must be very weak. But surely we might expect to attain better and more successful results by the application of electricity directly to the stomach. In his celebrated book on "Electrotherapy," Erb [8] says: "The first maxim to observe is the treatment in *loco morbi*, *i.e.*, the application of electricity to the morbid part itself. . . . There is no doubt that it is best, in the great majority of cases, to operate directly on the diseased spot."

Pepper [9] had a patient with dilatation of the stomach, in whom the abdominal walls were so thin that the spontaneous peristalsis of the stomach could be perceived. On this patient he showed that electricity, percutaneously applied, never produced any peristaltic movements of the stomach. Pepper then continues as follows: "The difficulty of compelling a current, no matter what may be its strength, to penetrate through various layers of tissue of different consistency and anatomical character is well known." Speaking of the percutaneous electricity of the stomach, Kussmaul [10] remarks: "The therapeutic results obtained by Fuerstner and others in cases with dilatations of the stomach do not prove that by means of the current a direct peristalsis of the stomach was induced, but could be attributed to the favorable influence of the contractions of the abdominal walls." All the sentences mentioned plead for applying electricity to the stomach directly, and not percutaneously, if possible.

Canstatt [11] first proposed to combat dilatations of the

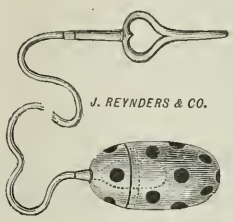
stomach by direct electrization, introducing one electrode into the œsophagus and putting the other in the stomach region. Duchenne [1] was the first who made use of this method. Very soon afterward, in 1877, Kussmaul [2] began to practise the direct electrization of the stomach. The electrode used for the purpose consisted of a stomach-tube, through which ran a copper wire ending in an olive point and fastened to the cut-off end of the tube. In several patients with dilatation of the stomach Kussmaul introduced this electrode into the stomach, the other (ordinary) electrode being held in the hand. In applying electricity in this way contractions of the abdominal muscles on the left side appeared, and in one patient, with thin abdominal walls, contractions of the stomach were visible on applying weaker electric currents. Kussmaul speaks very highly of this method for the direct electrization of the stomach.

Later on Balduino Bocci,[3] in 1881, experimenting on animals, was persuaded "that the indirect faradization of the stomach through the abdominal walls produces in the stomach, even when applied in a very energetic way, phenomena of very little importance, and of a dubious curative effect." As the direct faradization of the stomach, on the other hand, showed all the above-mentioned physiological effects, Bocci recommended anew the use of the direct electrization of the stomach for therapeutic purposes. Bocci used for this end an electrode like that of Kussmaul.

Great progress in the direct electrization of the stomach was made in 1884, by G. Bardet.[4] The direct contact of the lower metal piece of the electrode with the inner wall of the stomach irritates only a small spot, and this very intensely, whereas the larger part of the stomach receives but very little of the electricity produced; in consequence thereof the galvanic current could not be applied, because by the usual method it would not be possible to avoid lesions of the mucous membrane of the stomach. In order to overcome these drawbacks Bardet constructed his stomach electrode in such a way that the metal-piece running through the tube was shorter than the tube, and did not touch its windows. By filling the stomach with water the electric circuit between the stomach-wall and the lower metal-piece of the electrode was established. In this way the electricity was distributed over the whole surface touched by the water. By means of this electrode Bardet treated three cases of dilatation of the stomach, and one case of obstinate vomiting, with the galvanic current (15 to 25 milliampères) and obtained splendid results. Most authors who employed the direct electrization of the stomach have, until now, generally used Bardet's electrode. (Charles G. Stockton's [6] stomach electrode does not differ very much from that of Bardet.)

Although the high value of the direct electrization of the stomach is self-evident, this method did not enter much into practice, because the tube surrounding the electrode had to be kept in the throat during the whole electric session (about ten minutes) and inconvenienced the patient to such a degree that the procedure could be carried out only in people accustomed to lavage of the stomach, and even by them it was disagreeably felt. That is the reason why von Ziemssen [6] rejected direct electrization of the stomach as being too straining and exhausting. Ewald,[7] notwithstanding these difficulties, recommends it. In the same way Charles G. Stockton,[8] in his elaborate paper entitled, "Clinical Results of Gastric Faradization," highly recommends the use of direct electricity in cases of dilatations of the stomach and in many functional disturbances of this organ. Boas,[1] on the other hand, is conservative as regards the use of direct electricity for the stomach. This author gives in his book, "Diagnostik und Therapie der Magenkrankheiten," a drawing of the stomach-electrode generally in use, which consists, as described above, of a stomach-tube, through which runs a fine spiral wire ending in a metallic button within the tube.

In order to facilitate the internal or direct electrization of the stomach I have constructed an electrode on the same principle as the stomach bucket designed by me.[2] This electrode once swallowed reaches the stomach without further artificial aid. The silk thread of the bucket is represented in the electrode by a very fine (1 mm. in diameter) rubber tube through which a very fine, soft, conducting wire runs to the battery. The end-piece of the electrode consists of a hard rubber capsule (of the same size and shape as the stomach bucket) with many openings. In this capsule lies a metallic button which is connected with the wire. (Figure shows the electrode in natural size).



The rubber capsule serves to avoid the direct contact of the metal with the stomach-wall; the circuit is completed in the same way as in Bardet's electrode, by the water the stomach contains.

This electrode might be aptly designated a "Deglutable Stomach Electrode." [3]

Method: The patient drinks, best when in a fasting condition, one to two glasses of water (tea, coffee, or beer). The patient has now to open his mouth widely, and the electrode (the capsule piece) is placed far behind on the root of the tongue and he is ordered to swallow. He again drinks some water, and the electrode finds its way to the stomach without any further assistance.

In order to recognize this point precisely, it is advisable to make some mark on the cord at a distance of 40 ctm. from the capsule; as soon as this mark comes to the teeth we are sure that the electrode is in the stomach and we can apply the electricity to the patient.

The other (ordinary) electrode is best placed either on the back to the left of the seventh dorsal vertebra, or in front at the epigastric region, or is simply held in the hand. In cases where the stomach and intestines have to be electrized, it is advisable to use as second electrode a very broad one (the so called "plate electrode"), and to keep it on the abdomen.

In withdrawing the electrode a resistance is felt at the introitus œsophagi; it is not advisable to pull the electrode with force. One has only to make the patient swallow once or twice, and to make use of the moment when the larynx, by this act, ascends and the passage becomes free, to withdraw the electrode, which is done now with perfect ease.

Direct electrization of the stomach by means of the deglutable electrode is very simple and handy for the patient and for the physician, and, as it seems to me, as easy to apply as percutaneous electrization. Considering the great rôle electricity plays in medicine as a therapeutic means, it has been perhaps to a certain degree neglected in the treatment of stomach and intestinal disorders, because a handy method for the direct electrization of the stomach was wanting.

I hope after a while to be able to give a detailed account of the physiological effects of direct electrization

of the stomach in man. To-night I would like to describe a few experiments which tend to prove that the gastric-juice secretion is increased by direct electrization of the stomach.[1]

The investigations have been made in the following way: Three persons not having any complaints in reference to their digestion were examined, when fasting, with the tube, in order to see whether the stomach was empty or not, and if not, then it was emptied. Thereupon each one of them drank 100 or 160 c.c. of water and swallowed the stomach electrode, electricity, however, not being applied. After ten minutes the electrode was withdrawn and the stomach contents emptied by means of a tube, and examined in regard to hydrochloric acid and to the degree of acidity. Thereupon the same trial-subjects had to drink again the same quantity of water, and the stomach was now faradized (the deglutable electrode being in the stomach, the other in the left hand) not very strong for ten minutes; then the contents were obtained, examined, and compared with the first portions.

The trials were as follows:

I.—T. N——, physician, twenty-eight years of age; September 10, 1890; when fasting; stomach empty.

1. Drinks 100 c.c. of water and swallows the electrode. After ten minutes the electrode is withdrawn, and about 50 c.c. of the stomach contents are obtained. Reaction = acid; HCl + weak; acidity = 12.

2. Drinks 100 c.c. of water, swallows the electrode and gets faradized for ten minutes. The electrode is thereupon withdrawn and 40 c.c. are obtained by means of a tube. Reaction = acid; HCl + ; acidity = 16.

II.—T. S——, fifty years of age; September 23, 1890; when fasting; stomach contains about 5 c.c. of mucous secretion, with presence of HCl.

1. Drinks 160 c.c. of water and swallows the electrode. Ten minutes later the electrode is withdrawn and 140 c.c. obtained. Reaction = weakly acid; HCl with Congo = no reaction, with Günzburg's test = ?; acidity = 4.

2. Drinks 160 c.c. of water and is faradized. After the swallowing of the electrode, for ten minutes the obtained quantity = 170 c.c. Reaction = acid; HCl, Congo paper turns blue on the margin, Günzburg's test = + (even when twice diluted); acidity = 8.

III.—H. R——, twenty-two years of age; September 24, 1890; when fasting. There were obtained 3 to 5 c.c. of stomach secretion, with H Cl = 0.

1. Drinks 100 c.c. of water, and swallows the electrode. Ten minutes later there were obtained by the tube — 80 c.c. HCl + ; acidity = 8.

2. Drinks 100 c.c. of water, and is faradized. After swallowing the electrode for ten minutes the obtained quantity = 100 c.c. Reaction = acid; HCl + ; acidity = 12.

In all three experiments we find a higher degree of acidity in the second part of each trial, when faradization was applied, than in the first part, during which everything had been done just in the same way minus electricity. The conclusion that the faradic current increases the production of the gastric juice, therefore, seems to be justifiable.

As to the clinical cases treated after this method of direct electrization of the stomach, I would not like to trouble you at present with detailed accounts. However, I cannot abstain from giving you in a few words a *résumé* of my clinical experiences since September last.

The direct faradization of the stomach has been applied in:

(*a*) Three cases of hyperacidity; (*b*) five cases of dilatation of the stomach (caused by insufficiency of the motor power); (*c*) five cases of chronic gastric catarrh (or, more correctly, of gastritis chron. gland.) with diminished acidity; (*d*) one case of atrophy of the mucous membrane of the stomach.

[1] Remark. As regards the physiological action of direct electrization of the stomach in man, there have been as yet, so far as I could see from the literature, no investigations made.

The galvanic current has been applied internally in two cases of very severe gastralgia.

The most marked results have been obtained in all cases of dilatation, and in the grave cases of chronic gastric catarrh. The ameliorated condition was not only a subjective one, but could often be proven also objectively by the change in the chemical analysis of the stomach contents. In two cases of very aggravated chronic gastric catarrh, in which free hydrochloric acid could never be found after the test-meals, the same could easily be detected after the stomach had been faradized internally for ten minutes.

The majority of cases of hyperacidity (not combined with dilatation) likewise showed an improved condition. Here, by electricity alone, I seldom succeeded in diminishing the abnormally high degree of acidity. In order to fulfil this purpose I had to give the alkalies in the usual way.

The two cases of pure gastralgia showed an amelioration from the constant current, *i.e.*, first a decrease and then a disappearance of the attacks of pain, after the current had been applied for about two or three weeks, although it is certainly impossible to say for how long after such an electric cure the gastralgia will not reappear.

From the above it is evident that we possess in the direct electrization of the stomach a very potent means of overcoming certain abnormal conditions, and thereby permitting the functions of the stomach to adjust themselves to the normal. Let me, therefore, hope that this easy way of applying electricity directly to the stomach by means of the deglutable electrode, will tend to bring this remedy more into use among the medical profession.

120 East Sixty-Fourth Street.

STUDIES ON THE INFLUENZA AS OCCURRING IN RUSSIA.

By C. A. SIEGFRIED, M.D.,

Surgeon U.S.N.

Under instructions from the French Minister de l'Instruction publique, Professor M. J. Teissier, of the Lyons Faculty of Medicine, has collected a number of documents and writings upon the late epidemics of influenza, or grippe, as observed in Russia, and has published a *résumé* of his report in the January number of the *Annales a Hygiène publique*. The *Revue Scientifique* of April 11th also contains a synopsis of these reports, official and otherwise, of much interest from the many facts brought together and the hypotheses regarding the etiology of the at present widely prevailing, yet still unknown, disease.

It may be said that the two opposing views regarding the etiology of influenza—one in favor of purely physical causes, meteorological, the other a bactericidal—are both seemingly based upon good grounds. Yet those believing in a primary bacterial cause can reasonably and analogously explain the ordinarily observed tracks of the disease, even though there are instances of ships far at sea taking the epidemic disease by the communication of ordinary intercourse; and the wide stretches or jumps occurring are not inconsistent with the known facts of germ transmission in air-currents, the wafting of organisms over wide areas of sea and land having been observed since the time of Ehrenberg.

When we see so much written upon the diplococci, the streptococci, and the pus organisms, in connection with influenza, and with so much vulnerable method and report, one gains very little that is original, for these organisms can be found in the majority of cases of disease of the lungs and air-passages, and even in the comparatively well. Besides, streptococci means nothing more definite than small cocci in chains, which may be variations of one organism according to environment; or, according to Klein, any one of the seven or eight varieties he has apparently isolated in his recent studies on the exanthema

tous fevers in connection with such diseases as foot-and-mouth disease and diphtheria in cows and cats. Klein believes that eventually we will be able to differentiate the streptococci, and that varieties of this organism will be found to be the cause of scarlatina, variola, and the simpler forms of exanthematous fevers.

It would seem to be highly probable that the primary cause of influenza or grippe is an as yet unknown obligate parasite—obligate in the sense of not having been cultivated outside the human body—apparently needing the influence of unusual meteorological changes and conditions for its potential development. In conjunction and mutual reaction with it is observed unusual malignancy of several of the commonly known organisms ordinarily infesting the mouth and air-passages and which multiply disastrously in the various structures of the body on these occasions. On this hypothesis the diverse symptomatology of the disease becomes at least clearer, and the following notes furnish much affirmative evidence.

In the Russian very widely spread epidemics of 1889–90 there was observed no great difference from former great epidemics, though some observers state that there was somewhat less malignancy than in the epidemic of 1847, in which were very many cases of cerebro-spinal meningitis complication. If there were any doubts in diagnosis it was only in the first days of the epidemic, at which time many cases were of the nervous form, but shortly the medical faculty pronounced it "La Grippe." Some eminent men make the distinction and say there is no identity between grippe and influenza and some other infectious diseases. And again, in certain countries there is some confusion owing to the contemporaneous existence of dengue. MM. Herman and Kuznetzow speak of a certain resemblance between dengue, as observed in 1889 in Syria, Turkey, and the Isles of Greece, and grippe, both in its mode of propagation and its manifestations. Like grippe, dengue suddenly attacks whole communities—in Smyrna thirty thousand in a few days; it begins with great heat, head symptoms, nausea, vomiting, and violent general pains, and declines in three or four days by lowering of temperature and abundant perspiration. The difference, however, is marked by the, in dengue, joint-pains, knees particularly, and an eruption, either scarlatiniform or rubeoloid, and desquamation. But in some rare cases of grippe pains in joints and knees and the scarlatiniform eruption are noticed. The essential distinction, however, in the two diseases consists in the difference of the means of propagation, the grippe invading cold countries and dengue tropical and subtropical countries. The contagiousness of dengue is not of diagnostic value according to the above observers. they being believers in the probable contagiousness of grippe or influenza.

M. Herman, of St. Petersburg, reports the grippe of 1889 as coming from Siberia, as on previous occasions. Professor Jansen thinks the evidence as to this incomplete. M. Heyfelder believes it came from Bokhara, the first case being observed there in May, and it then travelled westward into Russia in Europe along the new railways. He reports cases among employees of the government railways, characterized by all the well known symptoms, some accentuated by intensity of nerve phenomena, delirium, depression, nausea, and offensive perspiration. As early as June half of the population had been attacked. Among the complications observed in Bokhara were hemorrhages and such severe purging and spasm as to simulate cholera Asiaticus. Heyfelder, observing similar cases in St. Petersburg, affirmed their identity, and notes also the limited number of catarrhal phenomena in the Bokhara cases. He cites the appearance of the epidemic at Viatka by October 1st, at Tomsk, October 16th, where it was known as "Siberian fever." It was then reported along all the post towns and stations in its extension westward to St. Petersburg.

All of these Russian accounts are highly interesting, in that the epidemic is fully and accurately observed in its appearance, rapidity of diffusion, and general notable tendencies. There is a concurrence as to its origin in Asia in the early summer of 1889, and by September it prevailed in St. Petersburg and Moscow. It is also asserted that sporadic cases prevailed in lower European Russia in April of the same year (?). The official documents are in accord in recognizing the endemic character of "la grippe, or influenza," in Russia. The reports of departmental medical officers, to the Minister of the Interior state the existence, in 1886, of 52,570 cases of grippe, and in 1887, of 43,943. From the sanitary statistics of the St. Petersburg & Varsovie Railway for the years 1885–1888, it is shown that fifty per cent. of the cases of illness among their employees (who are particularly exposed to the influences of contagion) were due to grippe. These facts go far toward establishing the contagiousness of the disease. Thus it appears that grippe, or influenza, has long been an endemic disease in Russia and countries under her control. "Siberian fever," "Mal Russe," etc., are names common for it in those countries.

M. Lipski argues that purely physical causes play an important rôle in the rapidity of its propagation, and mainly great temperature variations and the direction of the winds. In most epidemics it has been observed that great perturbations of weather have preceded them. Impure water supplies and the presence in the atmosphere of unusual forms of micro-organisms of a pathogenic character are dwelt upon. A series of low barometric pressures, with cold, has marked the commencement of many epidemics; yet exceptional instances are known in which the reverse conditions prevailed, but with an influence on the mortality rate of a favorable nature. Low pressure with abnormal heat has been noted. In all epidemics low pressure with persistent abnormal temperature and great humidity have been noted. Cessation of epidemics has always occurred with the advent of snow in regular seasonal change, in which French observers concur.

Studying the bearing of the water supply of cities and towns affected some remarkable facts are brought out. The water of the Neva contained, in November, 1889, 15.50 parts per 100,000 of organic matter, in place of 10 parts per 100,000 in September. In Varsovie the water of the Vistula contained twenty-one millions of bacteria per litre during the October preceding the epidemic, the figures declining to 1,008,000 per litre in November, and still less with the cessation of the disease in December. Further, the analysis of the waters did not establish any noteworthy facts.

According to the minute researches of M. Baboukhine, relative to the air of the Moscow hospitals and the water supply of the city, he demonstrated, in 1889, the unusual presence of the streptococcus of erysipelas, also numbers of usually absent colonies of bacteria. In 1888 and 1890 he observed no such peculiarities, and the singular fact of such concomitant conditions in 1889 is remarkable. His methods of procedure and analysis were uniform for the three years.

M. Teissier believes that impure water is an etiological factor of importance in influenza, noting that in the quarter of St. Petersburg where the supply is poorest—a water rich in bacteria, though otherwise the hygiene is fairly good—influenza always appears first. In Moscow and Varsovie similar facts are brought out, the poorer inhabitants along the river banks being the chief and worst sufferers. In the house of the French Consulate in Varsovie, situated in the midst of the epidemic area, no cases occurred, the water supply being pure and the same as supplied Gatchina, where no influenza existed until the arrival of a case from St. Petersburg, a perfect example of infection of a whole community by a single case. At Moscow, a mill employing two hundred hands had only a few and mild cases, the water supply being from deep artesian wells, whereas in a similarly situated mill using the common city supply of water the epidemic had full sway. The workmen in both mills were living in similar

unhygienic surroundings in their homes, the only difference being in the water supply. In the province of Kiew M. Losch finds the first cases among the inhabitants of the low-lying river banks of the Dnieper.

Two questions or propositions stand out clearly from these Russian accounts—the apparent means of propagation and diffusion of the disease and the relation or connection with other infectious diseases.

Most Russian medical men are disposed to admit the contagiousness of influenza from the number of highly attesting facts they can adduce. At the Wurtzburg clinic, cited by Leube, the entrance of a single case infected a whole ward; and at Kharkoff, MM. Herman and Kuznetzow report many examples. Zdekauer narrates that at Gatchina, where not one case had yet been known, a high military personage arriving was the same evening in his bed with severe influenza, and from that day all his suite and attendants gradually became ill, as well as the military men who came to advise with him. M. Jansen's writings seem to establish the contagious character of the disease, as well as its mode of propagation and diffusion by the ordinary methods of communication by sea and land, and from the secondary points of departure, laterally, from the common great track of the epidemic. From St. Petersburg and Moscow it rapidly went to Odessa, Varsovie, and Stockholm—all cities in direct communication with the capital and Moscow. In less than a week it appeared in Berlin and Paris, and from Stockholm to Christiana it required a month; rapid communication in the first place, a mountain barrier to overcome in the second. Once established in Berlin, Paris, and Vienna, it spread from those centres, like rays, in all directions. In early January, 1890, the highest mortality centres were in Paris, Kiel, and Vienna, a week later they had moved to the great centres of population of Great Britain, France, Spain, and Austria.

During the epidemic in St. Petersburg and Varsovie, other infectious diseases were nearly unknown. At Moscow, however, scarlatina and the other exanthems gained increased intensity and virulence. Erysipelas seemed to become almost epidemic at many points, concurring with reports from France. This is not simply a coincidence, but quite in accordance with observed facts in connection with bacterial infective diseases.

The official commission appointed for the purpose of studying the possible relation of cholera and influenza epidemics to each other concluded that there were no grounds justifying such a belief; and independently other observers, notably Smolenski, reached similar conclusions. This question was brought up in view of the facts observed in 1847, 1851, 1856, and 1865, on which occasions epidemics of cholerine regularly followed grippe. Smolenski showed that for six hundred and fifty years influenza could not be the precursor of cholera in Europe, since the latter disease was unknown for that time. In a number of years influenza and cholera were coincident, either preceding or following, oftener cholera following. From 1838–1845 there were a number of influenza epidemics and no cholera, and from 1869–1875 epidemics of cholera and no influenza. The great Asiatic cholera incursions or invasions of Europe of the years 1829, 1830, 1852, and 1865 were not preceded by influenza.

Quoting Smolenski still, the fear of cholera in 1890 was due to its existence in Persia and Mesopatamia in July, 1889. Cholera has appeared in Europe six times; in 1823, from Persia; 1829, from Turkestan; 1830, 1846, and 1852, from Persia; and in 1865 and 1884 by the Mediterranean ports. Each time, excepting only the first, these epidemics continued several years, and spread over Europe. Since 1883 Russia is in fear of cholera from both the east and west, and excepting the slight epidemic at Vladivostock, has thus far escaped. For thirty-seven years, however, the disease has not entered Europe from Persia. Most authorities confirm Gluge, who wrote in 1837 that cholera following the influenza in 1830 was simply a coincidence.

If the p... not yet been ... genetic elements of grippe, or influenza, have doubt. On the whole their existence is not left in much by these collected reports to considered as demonstrated disease is added to or associated micro-organism of the elements, such as the streptococci, secondary parasitic pneumonia organisms, and which gives to the cocci, and clinical forms and characteristics, and determines its verse localizations and regional types. These secondary elements are of such importance as to dominate the symptomatology, and hence suggest precautionary means that may prevent or alleviate the intensity of the disease and obviate further complications. Phlegmonous inflammations, erysipelas, and pneumonias are intensified hence, as a result of commonly observed bacteria becoming augmented to a dangerous pathogenesis by the "intoxication grippale."

It is believed that upon the appearance of grippe unusual measures of public and private hygiene should be undertaken. The water and food supplies, the drainage, sewerage, clothing, and disinfection, general and personal, should all be attended to. Daily cleansing of the mouth and throat with a disinfectant lotion would be indicated.

The treatment by drugs did not much vary from that of other countries. Comparisons of clinical charts of cases, treated variously by drugs and without, showed no great difference. It was not demonstrated that any substance employed greatly influenced favorably any single feature of the disease. Most commendation and most observers favor sulphate of quinine as a remedy of real importance. Warm to hot baths in the early period of the disease are highly spoken of and, according to M. Manasseine, have an abortive influence.

The following table of drugs used in the empire, furnished by the Pharmacological Society at St. Petersburg, gives the treatment in synopsis.

	1888. Ounces.	1889. Ounces.
Sulphate of Quinine	2,470	6,185
Chlorohydrate of Quinine	1,016	2,178
Antipyrine	1,223	2,490
Phenacetine	330	487
Antifebrine	870	1,840

A THIRD SERIES OF PERITONEAL SECTIONS. COMPARATIVE STUDY OF ONE HUNDRED AND FIFTY-NINE CONSECUTIVE CASES.[1]

By HENRY T. BYFORD, M.D.,

PROFESSOR OF GYNECOLOGY TO THE CHICAGO POST-GRADUATE MEDICAL SCHOOL; CLINICAL PROFESSOR OF GYNECOLOGY TO WOMAN'S MEDICAL COLLEGE; GYNECOLOGIST TO ST. LUKE'S HOSPITAL; SURGEON TO THE WOMAN'S HOSPITAL OF CHICAGO.

The accompanying table of statistics represents a third series of peritoneal sections, continuous with two others previously reported to this Society.

Death Rate.—The first series contained forty-six complete and two incomplete operations, with a mortality of 17.08 per cent. for the whole number, or 10.85 per cent. for the completed operations. The second series contained fifty-seven completed operations, with a mortality of fourteen per cent. The present series contains fifty-two completed operations and two incomplete, with a mortality of 9.25 per cent. for the whole, or 5.77 per cent. for the completed operations.

It is interesting to note that all fatal cases but one occurred in the abdominal sections. There were in all forty-six completed vaginal sections, with one death, or a death-rate of 2.17 per cent. In one other vaginal section, I was unable to complete the operation for an intraligamentous ovarian cystoma, and then resorted to abdominal section with a fatal result. In one of the forty-six cases I was obliged to open the abdominal cavity to enucleate a large ovarian abscess while performing vaginal hysterectomy. The uterus was, however, removed

[1] Read before the Chicago Gynecological Society, April 17, 1891.

ried. This entirely per vaginam. The patient ...ominal section was a vaginal hysterectomy with...se, and is the only in- in addition done for another... are recorded for the same stance in which two ov...

patient on the ovariotomy.—My experience with ovarian

Abdom... been somewhat exceptional. If we exclude ...minal ovariotomies, the death-rate for all completed abdominal and vaginal sections in the three series would have been only seven and a half per cent. But the death rate for abdominal ovariotomies alone was twenty-two per cent. The explanation of this high percentage is found in the following facts: Of the thirty-five abdominal ovariotomies, ten were developed in the subperitoneal connective tissue, in one of which I had to leave a piece of the adherent capsule on the diaphragm. Nine cases, or over one quarter, were malignant, and six were dermoid, with seven dermoid tumors. In two of the malignant cases, and in one dermoid, the tumors were developed in the sub-peritoneal tissue. In the thirty-five cases all but ten were either sub-peritoneal malignant or dermoid tumors, or had intraperitoneal adhesions. Such a series could not be expected to give a low rate of mortality. My other abdominal sections were child's play to them. Another reason for the high death-rate is that I removed the smaller and less complicated ones by vaginal section, thus leaving the worst ones to be considered alone. On the other hand, I never lost a case of ovariotomy without adhesions, except the case of hemorrhage among the first ones.

Abdominal Oöphorectomy.—There are sixty-six cases of abdominal oöphorectomy in the three series, with four deaths, or six per cent. Three of these deaths were avoidable, and the mortality should have been but one and a half per cent. In the last series there were no deaths. Hysterorrhaphy was performed in four of these cases with the most satisfactory results.

Abdominal Hysterectomy.—Another interesting study to me has been that of the abdominal hysterectomies, of which there were fifteen completed operations, with one death, or six and two-thirds per cent., and three incompleted operations, all fatal. One of my greatest faults in my earlier operations was to operate upon everything, whether hopeless or not. The first hysterectomy reported in the first series was the first case I ever attempted. It was a large sarcoma with which another surgeon had refused to interfere after an exploratory incision. The operation lasted nearly four hours, and as I could not raise the tumor out of the pelvis, I had to amputate it on a level with the abdominal walls. The next incomplete case was the second hysterectomy I ever attempted. The right Fallopian tube contained half a pint of fluid and the left one a quart of fluid. I succeeded in amputating below the tumors, but could not get out the multilated left tube, which had burrowed between the folds of the broad ligament to the bottom of the pelvis. The other incomplete operation was in the last series. It was a sarcoma consisting mainly of two lobes, each of the size of a full-term pregnant uterus. It pressed against the diaphragm and liver, and extended down into the cul-de sac of Douglas. The bladder extended half way to the umbilicus. The omentum was adherent above, while below the tumor was developed in the broad ligament and firmly attached to the rectum. The bleeding was profuse. The patient died on the table. This operation, like the other two, did not exhibit its formidable character until it was too late to stop. In the last eleven cases I employed vaginal fixation of the stump, with ten recoveries and one death. Altogether I have now operated in fifteen cases by this method, with one death, or six and two-thirds per cent. My limited experience thus leads me to believe that abdominal hysterectomy for non-malignant cases is not the formidable operation it has been heretofore considered, and that its mortality should be but little higher than that of abdominal ovariotomy. The chief reason for the high death-rate is that the operation is seldom undertaken until the best time for an operation has passed. One of the most useful accomplishments of a gynecological surgeon is to be able to foretell at any early date the unfavorable progress of a fibroid tumor, so as to attack it early.

Notes of Interesting Cases.—I present the following notes of cases as of some interest:

1. Ovarian cystoma developed subperitoneally, filling pelvis. Unable to get it out. Tore into rectum. Profuse hemorrhage. Could not find all the sources of hemorrhage. Could not find either uterus or ovary. Exposed the left ureter. One Fallopian tube almost the size of a man's wrist, and filled with cheesy substance. Stitched the sac of one cyst in the external wound. Three drainage tubes, one to each side, and one to the cul-de-sac of Douglas. Time of operation, five hours. Could not close sooner on account of continuing bleeding. Death in three hours from shock and anæmia.

2. Myomotomy and oöphorectomy. Removed a subserous pediculated fibro-myoma size of fist, from a large fibroid uterus filling pelvis. Dug the enlarged appendages out of solid beds of intestinal adhesions. Amputated a large piece of diseased omentum. Attempted to enucleate the uterine fibroid mass from pelvis, but was obliged to desist and leave them. Morphia, gr. one-fourth, hypodermically six hours after operation. Commenced the administration of salines fourteen hours after operation and secured an evacuation eighteen hours thereafter. The patient would undoubtedly have died had I removed all of the diseased tissue. Is now in good health five months after operation.

3. Patient had pelvic abscess several years ago. Bedridden for three years. Found stump of left Fallopian tube entering a mass of matted intestines. Did nothing but remove the cystic ovary from right side, of which she had not complained, and separate the intestines on the ailing side, enough to learn that the left ovary was not there. Patient was told that everything had been fixed all right, and got up from the operation and went about like other patients. In other words the belief that all was right cured her of symptoms that had outlasted the disease by several years.

Drainage.—In the first series I drained ten times in twenty-seven abdominal sections; in the second series, twenty-four times in forty-one; in the third, twenty-five times in forty-four. Thus in one hundred and twelve cases, I drained fifty-nine times, or in a little over fifty per cent. This seems like a great deal of drainage, but is accounted for by the gravity of the cases. I drained in all cases when much bloody effusion was to be expected, and always gave drainage the benefit of the doubt. The only serious objection I found to drainage was the liability to hernia. I always use a glass tube, which is removed in twenty-four to forty-eight hours, and usually a strip of iodoform gauze put in its place for eight or ten hours.

The assertion so often made that it is dangerous to use the drainage-tube is very difficult to answer by argument. According to my experience it has not added materially to the risks, but is dreaded by me on account of the trouble it gives me in superintending it afterward.

Among my earlier cases two patients died of hemorrhage that might have been saved had the drainage-tube been used. The fault should be attributed, however, to imperfect methods of placing ligatures. In the last one hundred and forty cases I have had no accident from slipping of ligatures, and do not ever expect to have one again.

In all other abdominal sections I drained in every fatal case, but do not attribute one death to it. In two or three of the cases that recovered suppuration in the track of the tube occurred, but this I think would have occurred anyhow, and might have been of greater consequence without the tube. Of the fourteen fatal cases in which the tube was used, one patient died in three hours with incomplete operation; another in ten hours; one in three and a half days of ileus; another in eight days of heart

disease, five days after tube was withdrawn, and absolutely without pelvic symptoms; another of exhaustion after four weeks, in which the autopsy showed the abdominal and pelvic cavity to have escaped sepsis or other complications; and another from a sponge left in the abdominal cavity after a long emergency operation.

Of the eight remaining to be accounted for four died in forty-eight hours from the severity of the operation, and required the tube for the removal of abundant effusions from disorganized tissue. One of the remaining died in six days of extensive adhesive peritonitis without effusion or sepsis. The tube had been taken out the day before death and might have been removed previously, as the serous discharge had ceased.

The other three died of septic peritonitis; one in six days, three days after the tube had been removed, and because not enough rather than too much drainage had been used. It was for ovarian abscess that burst in the abdominal cavity, and a septic focus was found post mortem at a distance from the tube. One of the other two died in four days with purulent peritonitis developed under the incision above the tube, the parts about the tube were not thus affected. The only case in which I could see any connection between the drainage and the sepsis was that of a sarcoma, about the size of a six months' fœtus, which was injured at the operation and which could not be removed. The wounded area was under the incision and entirely shut off from the peritoneal cavity by a strip of gauze placed on it and brought through the adjacent incision. Death occurred in sixty-four hours. In other cases where I have slightly wounded a vascular tumor that could not be removed, I have disinfected and dried the wound by a momentary compress of Monsel's solution and water, one to four, and have then either placed omentum or abdominal wall over the area, and closed the abdomen as aseptically as possible.

But while I attribute only one death possibly to drainage, and that to an extraperitoneal piece of gauze, I am sure that I should have lost some that recovered had I not drained.

In vaginal hysterectomies I drained in all cases, and in vaginal oöphorectomies and ovariotomies in all cases with adhesions. Drainage is here quite safe if properly carried out. It is a mistake, however, to carry the gauze or drainage-tube high up into the peritoneal cavity, as this might give rise to sepsis, peritonitis, or ileus. The peritoneal cavity should be closed, except a small area at its bottom, and the gauze or tube placed as a rule only far enough up to reach the serous cavity and drain all that settles there. All stumps that are to slough off should be pulled down to or near this outlet.

Comparative Study of Fifty-four Peritoneal Sections.

	Operations.	Recovered.	Died.	Per cent. Recovered.	Per cent. Died.
Hysterectomy	10	9	1	90	10
Oöphorectomy	16	16	0	100	
Ovariotomy	11	10	1	90.91	9.09
Myomotomy and Oöphorectomy	1	1	0	100	
Nephrectomy	1	1	0	100	
Pelvic hæmatocele	1	1	0	100	
Drainage of abscess	1	1	0	100	
Exploratory incisions	2	1	1	50	50
Incomplete operations	2	0	2		100
Vaginal Sections.					
Hysterectomy	8	8	0	100	
Ovariotomy	1	1	0	100	
Total	54	49	5	90.75	9.25
Mortality for completed operations	52	49	3	94.23	5.77

Hernia.—Small hernias occurred in three cases: one oöphorectomy, one ovariotomy, and one hysterectomy with abdominal fixation of stump. In each case it occurred at the site of the drainage-tube or stump.

Salines.—I have used opiates very seldom, and salines quite frequently. One or two hyperdermics of morphia were sometimes required to keep the patient quiet during the first six or eight hours after the operation. Its bad effects were quite satisfactorily counteracted by a subsequent saline laxative.

I have not derived the satisfaction from the saline treatment that I have been led to expect. In two or three cases it seemed to increase the extent of the peritonitis, and in others it complicated the convalescence by inducing irritability of the stomach and bowels. In severe septic cases it was utterly useless. In tympanites laxative enemas often act more promptly and efficiently. But in ordinary cases with a tendency to intestinal paralysis and perverted secretions it acted charmingly, and is a valuable addition to the after-treatment of abdominal sections.

There is no doubt in my mind that our late beloved Professor Parkes was right when he said to us a few months ago in this room that the less we do to the patient after abdominal section the better. If they are going to get well they will, if not they won't.

INTERESTING MEDICAL CASES.

By HENRY A. RILEY, Esq.,
NEW YORK

Life Insurance and Eyesight.—The vagaries of life insurance are remarkable, and the miserable shifts some companies make to avoid the payment of policies would be laughable were they not the cause often of serious trouble to the families of the insured.

A curious case of the kind occurred not long since in Pennsylvania, where a person was insured against accidental death and permanent disability in the sum of $1,000. the policy providing, among other things, that the whole of the sum should be payable in the event of the "total and permanent loss of the sight of both eyes." Before the insurance was obtained the plaintiff had lost the sight of one eye, which fact was known to the general and to the soliciting agent of the company.

Subsequently the plaintiff lost the sight of the other eye, but the company refused to pay on the ground that he had not lost the sight of both eyes after the insurance was effected. The court refused to take this view of the matter, and directed that the judgment against the company should be affirmed. The opinion stated the decision as follows: "The loss of one eye to him was precisely the same as the loss of both eyes by an ordinary man. It is total blindness in either case. There is no provision in the policy for the loss of one eye, as there is for the loss of one arm or one leg. The reason is plain. The loss of one eye does not produce a 'total and permanent loss of sight.' For all practical purposes a man with one eye can still follow his occupation and gain his living, while the loss of an arm or a leg is a disability which seriously interferes with his ability to earn his bread; hence it was that the policy provided, or rather, defined, the 'loss of sight' as the loss of both eyes. It was the loss of sight which was insured against, and this was just as complete in the plaintiff's case as though both eyes had been lost during the life of the policy. Assuming that the company intended to insure the plaintiff against something, and that something was the loss of his sight, the most that can be said is that, having but one eye, the risk was increased; but the risk was not increased after the policy was issued."

The Value of Coroner's Juries.—The utility of coroner's inquests has been frequently called in question, and quite a number of well-informed people have at various times endeavored to abolish the office and duties of the coroner.

It must be admitted that at times the verdicts of the juries which are empanelled are of very little value.

Take, for instance, the case of the New Orleans mob which shot down in cold blood the Italians confined in the city prison.

The form of having an inquest was gone through, but it was hardly expected that the jury would do much toward helping on a prosecution of the offenders. The public sentiment of the city ran too strongly in favor of the lynchers to make it probable they would do anything more than express ignorance on the subject of the guilty men, although many of them were well known. This expectation was realized, for the jury decided that the Italians came to their deaths at the hands of unknown persons. In this case, at least, coroner's juries proved of very little value.

In another instance, however, the coroner and his jury have done a good deal toward unravelling one of the most perplexing of recent murders. This was the recent death of two persons, one of whom was found drowned in the water on the Staten Island shore, and the other committed suicide at the Astor House, New York City. It seemed for a time that the identity of the persons as well as the offender, in case the Staten Island corpse came to his death by foul means, would never be discovered.

It now seems fairly certain that the drowned man was Ruttinger and the suicide his friend Wright. It is quite doubtful also if the drowning was not a willing act, although it would seem that Wright helped Ruttinger by putting a gag in his mouth.

The credit for these discoveries rests with the coroner and the newspapers, which have been very active in the effort to unravel the tangled threads of doubt and mystery.

One curious circumstance about the affair is the appearance of a new character in criminal annals. This is the professional identifier, as one Perrin H. Sumner may be appropriately termed. He has been very active in attempting to prove the identity, not only of the Astor House suicide, but of another suicide in Yonkers. His statements have been so numerous and so contradictory, and his whole conduct so unexplainable, that he has been regarded with great curiosity by the police and by criminal lawyers. He is now charged with corruptly attempting to procure testimony to support his theories, and as a result is under arrest.

American Patent Medicines and Food Products in Europe.—It was reported some time since that Italy was about to adopt legislation which would very materially reduce the importation of patent medicines from this country, but whether this was from a desire to protect the health of the inhabitants or was a suggested measure of retaliation for the damage done by the McKinley Bill, was not readily apparent. The dislike of patent medicines would not seem to be confined to Italy, however, for there is said to be a Bulgarian law which provides that, if a remedy of this character is advertised to cure a certain malady and fails to do so, the vendor of the remedy is liable for damages, and may also be sent to prison for a limited period of time as a punishment for publishing an untruth to the injury of the public.

It has been stated on very good authority that the importation of American food products, especially that of pork, into Germany, was prohibited not so much as a health measure as part of the protective scheme of the government. The ostensible grounds for the prohibition were that the live and dressed meat of the American pig were not properly inspected in this country, and were liable to spread disease. Minister Phelps has been active in the matter and has shown conclusively that the system of inspection is rigid, and consequently the German Government has been obliged to raise the embargo. If it had not done this it would in fairness have had to acknowledge that the prohibition was a protective measure, which was a position it did not care to openly assume.

An English Shooting Case.—The following is the summary of a recent English case as found in a legal journal: "The defendant, who was one of a shooting party, fired at a pheasant. One of the pellets from his gun glanced off the bough of a tree, and accidentally wounded the plaintiff, who was engaged in carrying cartridges and game for the party. The jury found that the defendant was not guilty of any negligence in firing as he did."

EXTREME CASES OF PTERYGIUM.

By G. STERLING RYERSON, M.D., C.M., L.R.C.S. Edin.,

PROFESSOR OF OPHTHALMOLOGY IN TRINITY MEDICAL COLLEGE, TORONTO, CANADA.

The rarity of cases of pterygium involving almost the entire cornea is shown by the following passage from Dr. Noyes' new and admirable work:[1] It is conceivable "that the most suitable way of dealing with an extreme case might be to perform iridectomy downward and outward, and the removal of the growth would be optional. *But I have never seen such a condition.*" The italics are mine and are made use of to emphasize Noyes' statement. The following cases, illustrative of this condition, have come under my observation. A West Indian merchant, of English descent, was sent to me in the summer of 1882 for advice. I found that he had a large pterygium growing from the inner angle of right eye, extending over the pupil. The direct vision was nil. By looking well upward, he could, by peripheral fixation, read $\frac{1}{4}\frac{5}{0}$ Snellen. As the pterygium had covered the pupil, a dense scar would be left behind on removal, so that I did not think that ablation would benefit him. I recommended and performed a small iridectomy downward and outward, with the result of a very considerable improvement of vision. He returned a few weeks afterward to Jamaica, and I have not heard of him since.

The second case is still under care. An Indian from the Grand River Reserve was sent to me by Dr. Langrill, two weeks ago, with a dense pannus crassus of left eye, both outward and inward, so that only a tiny triangular portion of clear cornea was left below, and a somewhat larger one above. V.L.=fingers at four feet.

On the right eye was a large pterygium growing from the inner side across the cornea, and covering the pupil. There was a small one on the outer side. The vision was very defective. He could count fingers at ten feet, but was doubtful about the test-types, because illiterate.

I did small iridectomies upward in each eye with gratifying results. I did not attempt to remove the pterygia in this case, because so large a portion of the cornea was involved, and because the growths themselves were so large that it would have been difficult to find flaps to cover the denuded surface.

I might remark in passing that the operation to be preferred, in cases of moderate-sized growths, is Jalezowski's.[2] I have performed it a great many times and have never seen any ill results. I have also performed Szokalski's operation several times, but one case was followed by extensive sloughing of the cornea, and I have not done it since. In larger growths I have found Knapp's modification of Desmarres' operation of transplantation very satisfactory.

63 College Street, Toronto.

Micro-organisms of Meningitis.—The following is a list of microbes stated by Adenot to have been found as the cause of disease in different cases of meningitis: the pneumobacillus of Friedlander, the pneumococcus of Fränkel, the intercellular diplococcus of Weichselbaum, the streptococcus pyogenes, the staphylococcus pyogenes, the tubercle-bacillus, the bacillus of typhoid, the pseudo-typhoid bacillus of Neumann and Schäffer, and the pseudo-typhoid bacillus of Roux.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 9, 1891.

THE STATE BOARD OF MEDICAL EXAMINERS.

THE *Buffalo Medical and Surgical Journal* is disappointed over the attitude of the New York weeklies toward the new Board of Medical Examiners. "The apparent grievance," it says, "of the MEDICAL RECORD is that the City of New York was not given the majority—or indeed any—representation on the State Examining Board, as announced in the newspapers. This is reviving the old sectional question that always springs up in the minds of some whenever anything is to be done in the way of making appointments; but, in this instance, we respectfully refer the RECORD to the Board of Regents of the University of the State of New York, where is vested the appointing power."

We are obliged to our esteemed contemporary for the reference; and are pleased to learn just where the trouble lies.

The Board of Regents of the University of the State of New York has been very much in print of late, to the great delectation of its secretary, who is an ingenious gentleman and much interested in the expansion of his functions. But we suspect that if things go on as heretofore the better the Board is known and the more it is expanded the less it will be liked. In the matter under discussion it is very well understood that the Board of Regents was very neatly handled by certain gentlemen, with the result that it appointed a Medical Examining Board very inadequately representing the profession of the State, and not representing the city of New York at all, where the chief part of our medical education is done. As a consequence the law is at once made unpopular, and a recent bill which was introduced to weaken it was promptly passed, meeting with but lukewarm opposition.

The medical colleges are no doubt delighted at the present turn of affairs, but the profession in general ought to and will feel strongly indignant at the stupidity and weakness of the Board of Regents.

We trust that our contemporary, the *Buffalo Medical and Surgical Journal*, knowing now where the trouble lies, will turn its powerful guns upon this Board, in the effort to persuade it hereafter not to be made a catspaw of by the astute politicians who run our medical colleges.

FOREIGN BODIES IN THE AIR-PASSAGES.

THE entrance of foreign bodies into the lower air-passages is not a very rare accident, especially in children, but it is always an alarming one. The danger depends, however, largely upon the size and character of the foreign substances. These are commonly fragments of bone, kernels of fruits and nuts, spears of grain, beans, peas, nut-shells, small stones, and coins. As the result of vomiting particles of food may enter the trachea, this accident being especially common in children and imbeciles (Riegel). Fragments of pharyngeal polyps, and of tonsils, teeth, pus, blood, and other results of local disease or surgical work in the upper air-passages may pass through the rima glottidis into the trachea.

Bryant records a case in which a piece of meat became impacted in the larynx, causing instant death.

Not long ago Wharton reported the case of a child of four who had got a large brass shawl-pin into its trachea which set up a fibrinous inflammation.

A bridegroom inhaled a rabbit-bone at his wedding-dinner. His honeymoon was interrupted by a combination of laryngo-tracheotomy and artificially induced emesis. St. Louis children seem to have a fondness for getting cocker-burs into the larynx. One physician, Dr. Glasgow, has seen and removed three of them. A patient of M. Godet's inhaled a leech and spat blood for twenty days, when he was relieved by a thyrotomy.

It is well known that in rare instances a foreign body may remain in the lungs for years and cause no symptoms. Dupuytren related a case in which a coin was retained for ten years, and Professor Gross had observed a case in which a bone was coughed up sixty years after it was inhaled! Such cases as these, however, mostly belong to older literature, before the time of the laryngoscope, and an element of doubt hangs about them. In recent times, Vainossy has reported the case of a tailor who got a needle into his lower air-passages and retained it there for ten months, when it was coughed up.

Foreign bodies in the air-passages are always very serious things for the patient, and call for courage, promptitude, and skill on the part of the surgeon. According to Mr. Durham's statistics, which include 636 cases, 41 per cent. die when no operation is performed, and 23 per cent. when surgical interference is undertaken.

Some addition to our therapeutic resources in late years has been furnished by cocaine and by the use of the O'Dwyer tubes, as shown in a case reported by Metzger.

The surgery of the trachea and bronchi has also become more perfect, so that most cases of foreign bodies in these parts can be successfully dealt with. The case of Dr. Bothwell, which is described elsewhere, was one of exceptional difficulty, owing to the fact that the foreign body was a cork that swelled and became tightly impacted.

MODERN DISCOVERIES OF NEW CURES.

WITH painful and patient pen we record the birth of a new treatment for phthisis, the sixth in four months. The hopeful author and discoverer this time is Dr. Tranjen, of Sistow, Bulgaria. He doesn't seem to have any front name, but that may be the fashion in Sistow. Professor Dr. C. A. Ewald writes a supplement to Dr. Tranjen's

communication and also publishes the details in all their rosy tabulated promise in the *Berliner Klinische Wochenschrift*, an organ for practical doctors. The refrain which Dr. Tranjen plays upon Professor Ewald's organ is like that of the other discoverers. We are having prepared lithographed forms for the benefit of future ingenious therapeutists in this same line. It will read like this:

"*Form* I.—Dr. —— has discovered a new remedy for phthisis. He reports . . . cases. The results have so far been very satisfactory. In early stages it produces decided improvement and sometimes cure. In later stages it does not do so much good, but sometimes causes remarkable improvement before the patient ultimately dies. Dr. ——'s new treatment promises to be a useful addition to our therapeutic armamentarium, and deserves further trial."

We shall be very glad to furnish "discovery blanks" of the above type to our clinical workers.

But meanwhile we had almost forgotten to say that Dr. Tranjen's new discovery consists in the hypodermic injection daily, for seven to ten days, of a solution of thymolo-acetate of mercury, at the same time giving the patients iodide of potassium. The results are accurately described in Form I. as above given.

A STUDY OF CONSANGUINEOUS MARRIAGES.

THERE is a little commune, known as Fort Mardick, on the extreme northern coast of France, where nearly all the inhabitants are related to each other, almost all of them having sprung from four families who settled the place originally. As their neighbors were of a different race and language (Flanders), it is very probable that most, if not all, of the early marriages in the community were among blood-relations, and even now twenty-four per cent. of the marriages are between cousins of not more than two removes. Such a community ought to furnish valuable material for the study of the effects upon the offspring of consanguinity among the parents, and, indeed, the study has been made by Drs. Louis and Gustave Lancry, a reference to which we find in *L'Union Médicale*, No. 24, 1891. These observers found that there had been sixty-three unions of this sort from 1882 to 1886, or more than twenty-four per cent. of the entire number—a very large proportion indeed, considering that the percentage for the whole of France is less than three. Inquiry was made concerning each of these families, with the result of revealing only two defects in the children. In one family there was a deaf mute, and in another an idiot. The deaf-mute had lost his hearing at the age of three years, but previous to that time had been able to talk as well as other children of his age. The mother of the idiot had met with a terrible accident whereby she nearly lost her life while she was carrying the child, a fact that would probably have been accepted as a satisfactory explanation of the defect in case the parents had not been related.

The Drs. Lancry also endeavored to learn what effect, if any, consanguinity had upon fecundity. They found that, of the total number of marriages in the commune between the years 1882 and 1886, 10.4 per cent. of the couples were sterile, while 4.3 per cent. had had but one child. Of the consanguineous marriages 16 per cent. were without fruit, and in 7.95 per cent. there had been one child.

As a result of their studies the authors come to the conclusion that the marriage of blood-relations tends to the diminution of the birth-rate, but that it has no prejudicial influence upon the children that may be born in such unions.

News of the Week.

A Case of Leprosy, in the person of a Greek pedler, is said to have been discovered in this city.

Dr. Sylvester H. Hunt, of Long Branch, N. J., died on May 5th, aged fifty-four. He was born in Troy, N. Y., and graduated in medicine at Jefferson Medical College.

Dr. W. H. Bolling, one of the most prominent physicians in the South, and Dean of the University of Louisville, died May 5th. He was fifty-one years of age.

Dr. Hobart Amory Hare has been elected Professor of Therapeutics in Jefferson Medical College, to succeed Dr. Bartholow.

The New Medical Law in France.—A new law regulating the practice of the healing art in all its branches has recently passed the French Chamber of Deputies. The first clause enacts that "no one shall be allowed to practise medicine in France unless he possesses a diploma of Doctor of Medicine granted by the French Government after examinations passed before a state institution of superior medical education." This provision abolishes the lower grade of practitioners known as *officiers de santé*, due regard being, however, paid to the rights of those who are already in practice, or who have entered as students with the intention of obtaining that qualification. Foreign medical men, whatever be their nationality, will be allowed to practise only after having obtained a diploma of Doctor of Medicine from the French Government. It may be questioned, in view of the above, whether the United States, or the States individually, ought not to forbid Frenchmen from practising in this country without first securing a local degree.

New Medical Law of Alabama.—The Penalty Bill, as it passed the Legislature, provides that any person practising medicine or surgery in that State without having first obtained a certificate of qualification from one of the authorized Boards of Medical Examiners of the State, shall be guilty of a misdemeanor, and on conviction thereof shall be fined not less than twenty-five dollars, nor more than one hundred: Provided, that this act shall not apply to any doctor practising medicine in Alabama who is a graduate of a reputable medical college, and who has complied with the law by having his diploma recorded by the Judge of Probate in the county in which he is practising.

A Cure for Snake-Bite.—Australian physicians are reporting many cases of successful treatment of snake-bite by the use of hypodermic injections of strychnia in doses of gr. $\frac{1}{25}$. The snakes that bite are the "death-adder" and the black snake.

An Epidemic of Typhoid Fever has been attacking Philadelphia. Since January 1st there have been 1,502 cases and 311 deaths. The cause is believed to be the polluted water supply.

Dr. John Frederick May, an eminent physician of Washington, died on May 1st, of pneumonia, in the seventy-ninth year of his age. He was a son of Dr. Frederick May, of Boston, who went to Washington in the early part of the present century. The son graduated from Columbia College, and after a long course of instruction in medicine and surgery abroad, returned to Washington. He was one of the reorganizers of the medical department of Columbia University, in which he filled the chair of Professor of Anatomy and Surgery for many years. His skill and learning received broad recognition. He was the first American surgeon that ever made a successful amputation at the hip-joint.

Medical Legislation in New York.—Governor Hill has approved the bill exempting from the action of the Medical Licensing Board all medical graduates who began their studies previous to the year 1890. Consequently the Board will have little to do before the year 1893.

Death from a Cork in the Bronchus.—Much interest has been excited by the case of an eminent Brooklyn clergyman, who died on Sunday last from the effects of a cork accidentally inhaled sixteen days before. When Dr. Bothwell first swallowed the cork, he did not think it a serious affair. His efforts to extricate the cork with his finger only pushed it further down, and he believed for a time that he had gotten rid of it for good. He preached two sermons next day without any great difficulty, and it was not till Monday evening that he decided to see his physician, Dr. Rushmore. The doctor did not consider the case a serious one, and only after the usual methods of removing foreign substances from the throat had all failed did he begin to be alarmed. Dr. Bothwell was taken to the hospital three days later, and while there three operations were performed. Tracheotomy was finally resorted to, and a flexible silver corkscrew was pushed through the windpipe and an attempt was made with it to draw the cork. This experiment failing, it was decided to remove portions of two ribs and cut the cork out of the bronchus, but the sufferer did not rally sufficiently to stand the shock.

Sanitation in the Great West.—Our esteemed countrymen of Colorado may not be thoroughly and profoundly educated in the science of hygiene or the art of administering sanitary laws, but they have a crude sense of what is needed in these matters which is often more effective than a health board ordinance. A telegram from West Denver announces that the police were summoned hastily to that place, on May 2d, where a mob was in the act of lynching a Chinaman named Wing Lee. The neighborhood has been unhealthy lately, and an examination was made of the cellars occupied by several Celestials. The filth and stench were frightful, which so enraged the people that they procured a rope and would have hanged this particular Chinaman had not the police patrol wagon put in a timely appearance on the scene.

Dr. Abraham Coles, of Newark, N. J., died recently in California, aged seventy-eight. Dr. Coles was a graduate of Jefferson Medical College. He was a man of wide learning and much literary skill, and was the author of various works in medicine, science, and literature.

Cannabis Indica in Colic.—Dr. S. Stewart, of Nebraska (*Journal of Comparative Medicine*), gives two-drachm doses of fluid extract of cannabis indica every fifteen minutes for colic, and his cases recover. He gives it, however, to horses with colic only.

Virchow's Seventieth Birthday.—Several of the pupils and admirers of Rudolph Virchow have united in appealing to the medical profession of the United States and Canada for contributions to the fund which is being raised in Germany, England, and, it may be said, throughout the world, as a testimonial to be given to Professor Virchow on his seventieth birthday. The German committee proposes that the fund shall be used in procuring a large, gold portrait medal to be presented to Professor Virchow. Bronze replicas are to be given to each member of his family and to certain scientific institutions. The balance of the fund is to be transferred to Professor Virchow, to be devoted to such purposes as he may see fit. We take pleasure in calling attention to the circular now issued by the American committee.

VIRCHOW TESTIMONIAL FUND.
